Abstract:	The global threat posed by invasive alien plants has prompted inventory compilations and screening exercises that aim to understand invasiveness in various taxa. Various traits influence the invasiveness of a species but do not apply indiscriminately to all plant taxa. Ferns (Pteridophyta) are rare or absent from such inventories, but notable fern invasions do exist. We developed a global inventory of terrestrial alien ferns comprising 157 species, using published literature and online inventories. We aimed to determine which traits influence the probability that a terrestrial alien fern will become naturalised or invasive. Generalised linear models with transition stages as response variables, were used to assess the effects of various anthropogenic, biological and distributional traits on invasiveness. Our model explained 30-40% of the variance associated with invasiveness and showed that a geophytic life form, reproductive plasticity, tolerance for disturbance and varied light conditions, and a broad introduced range (interpreted as high environmental tolerance and popularity in horticulture) were important determinants of invasiveness in alien ferns. We highlighted which geographic regions and pteridophyte families had the highest incidences of alien ferns and identified particular species of concern. This study aids in the understanding of the mechanisms underlying invasiveness in alien ferns and the findings can inform future research on this understudied taxa as invasive species.

alien ferns, global inventory, invasion stage, introduced range, native range, reproductive plasticity

Introduction

1
2 Invasive alien species are one of the greatest threats to biodiversity, ecosystems and ecosystem services
3 (Millennium Ecosystem Assessment 2003). Species invasion generally follows a sequence of transitions (termed
4 the ‘introduction-naturalisation-invasion continuum’; Richardson et al. 2000) from introduction (i.e. species
5 introduced into an environment outside of its native range) to naturalisation (i.e. establishment of self-sustaining
6 populations) to invasion (i.e. the ability to expand its range beyond the initial site of infestation/colonisation)
7 (Falk-Petersen et al. 2006, Blackburn et al. 2011). The global significance of invasive species has prompted
8 inventory compilations and screening exercises as a means to provide information about the mechanisms of
9 invasion and inform sustainable management strategies, transforming the study of invasion biology into a
10 predictive science (Latombe et al. 2017; Pyšek et al. 2017). Global inventories of alien and invasive biota are
11 generally more comprehensive for faunal species (Pyšek et al. 2017) than for floral species. Inventories on alien
12 flora are generally poor in species composition and are restricted in terms of geographical scale (Latombe et al.
13 2017).

14
15 Pteridophytes (i.e. ferns) in particular, are rare or absent from inventories on alien flora for many parts of the
16 world. In a recent global inventory of naturalised vascular plants, ferns were absent from the list which comprised
17 200 of the most widely distributed naturalised plant taxa of the world (Pyšek et al. 2017). However, in a few
18 regions alien ferns rank amongst some of the most conspicuous, ecologically damaging, and well-studied invasive
19 species (Pemberton et al. 2002; Wilson 2002; Lott et al. 2003; Murakami et al. 2007; Chau et al. 2013). For
20 instance, of the Florida Exotic Pest Plant Councils’ (FLEPPC) list of category 1 invasive plant species (i.e.
21 “invasive exotics that are altering native plant communities by displacing native species, changing community
22 structures or ecological functions, or hybridizing with natives”), alien ferns comprise 12.5% of the list (FLEPPC
23 2017). In Florida the rapid invasion of *Lygodium microphyllum* (Cav.) R. Br. has infested more than 40 000 ha of
24 unique indigenous habitat (Goolsby 2004). The plants high climbing growth form allows it to fully smother forest
25 canopies and its rapid spread is facilitated by year-round vegetative growth and spore production (Volin et al.
26 2004; Robinson et al. 2010).

27
28 Various anthropogenic factors and environmental and biological traits have shown to be useful predictors of
29 species invasiveness (Kolar and Lodge 2001; Van Kleunen et al. 2010; Richardson and Pyšek 2012; Moodley et
30 al. 2016; Miller et al. 2017). Traits such as mode of reproduction, dispersal strategy, plant height, growth rate, and
31 environmental tolerance may provide alien plants with a competitive advantage over native species thereby
32 facilitating invasion (Kolar and Lodge 2001). In addition, certain environmental factors (such as habitat and
33 climate suitability, lack of competition, and presence of anthropogenic disturbance) may render an area susceptible
34 to invasion (Terazano et al. 2018). Propagule pressure and suitability for horticulture have been found to be
35 important determinants of invasion success (Carlton 2003; Dehnen-Schmutz et al. 2007) and relate to introduction
36 efforts by humans exceeding a plants’ natural dispersal capabilities. These effects, combined with longer residence
37 times (time since first introduction) usually correlate with the increased likelihood of plants becoming naturalised
38 or invasive and having larger areas of occupancy (Wilson et al. 2007; Van Kleunen et al. 2010). There are site
39 and invasion-stage dependent effects that influence the success of naturalisation or invasion in alien plants s
40 (Pyšek et al. 2012), and traits associated with invasiveness do not necessarily apply indiscriminately to all plant
41 taxa (Dawson et al. 2009; Moodley et al. 2016).

1 The majority of studies assessing invasive traits in alien plants focus on angiosperms as they are generally model
2 candidates for invasion but few studies have considered alien ferns even though their traits arguably present a
3 plant taxon with high invasive potential (Robinson et al. 2010). Ferns differ most notably from angiosperms in
4 terms of their reproductive systems by having two free-living generations namely gametophytes and sporophytes
5 (de Groot et al. 2012). They reproduce by means of intergametophytic mating and recombination, or by sustaining
6 homozygosity through intragametophytic selfing (i.e. self-fertilization of a single gametophyte) (Lloyd 1974).
7 Intragametophytic selfing is an important characteristic to consider with regards to invasive potential in ferns
8 because self-fertilization has been shown to be aligned with long distance colonization (Stebbins 1957). Spores
9 are able to tolerate unfavourable aerial conditions and once established, sporophytes display a high tolerance of
10 varying soil nutrient levels and have the ability to photosynthesise under low light conditions. Two pteridophyte
11 genera also show gametophyte revival after desiccation or dormancy (Page 2002). Ferns furthermore pose
12 resistance to predation, pathogens, and fungal attack through photochemical armament but benefit from plant
13 associations through the exploitation of mycorrhizae (Richardson and Walker 2010). Various ecological and
14 reproductive characteristics thus aid in the successful establishment of ferns in a wide range of habitats (Lott et
15 al. 2003), and despite their evident invasive capabilities, ferns are often overlooked as an invasive taxa.

23 Ferns have a long evolutionary history and are diverse with more than 12 000 known species. They inhabit a
24 variety of environments but pteridophyte diversity in terms of numbers of species, genera, and families, is
25 generally greater in regions with a higher evapotranspiration potential, annual precipitation and topographic
26 complexity (Kessler 2010). In wet mountainous areas ferns can represent up to 13% of the local flora with ca.
27 60% of Pteridophytes found in the wet tropics (Amaroso 2003). In contrast, ferns are virtually absent in arid zones
28 (with the exception of a few specifically adapted genera, e.g. *Cheilanthes* sp.) and are species poor in areas with
29 Mediterranean type climates (Ferrer- Castan and Vetaas 2005). Although species distribution and richness may
30 be influenced by environmental factors such as climate, topography and soil, fern occurrence and abundance may
31 also be largely influenced by the dispersal ability of a species (de Groot et al. 2012), source -sink effects (Leibold
32 et al. 2004), and anthropogenic influences (De Winter and Amoroso 2003).

39 Pteridophytes hold little economic value, therefore cultivation for purposes other than horticulture is unlikely
40 (Amaroso 2003). Since the early 1800s humans have moved hundreds of species of ferns out of their natural
41 ranges for horticultural purposes (Lowe 1864). Despite this it is estimated that globally only ca. 60 species of
42 ferns are problematic because of their invasiveness (Robinson et al. 2010). Given their diversity, wide-ranging
43 distribution and long horticultural history, pteridophyta seems to be a key taxon requiring systematic screening
44 for invasiveness and assessment of traits associated with invasiveness. Our objectives were therefore to (i) develop
45 a global inventory of terrestrial alien ferns using literature and online inventories; (ii) determine the invasion status
46 of each species; (iii) determine which traits (i.e. including. ecological, biological and anthropogenic) influence
47 the probability that a terrestrial alien fern will become naturalised or invasive, and (iv) highlight problematic
48 species and families to inform future risk assessments.

55 **Methods**

57 *Inventory, geographic distribution, and family representation*

1 In order to develop a global inventory of terrestrial alien ferns we surveyed various available sources which
2 included: published literature; herbarium records; alien and invasive plant lists e.g. FLEPPC
3 (<http://www.fleppc.org>) and Southern African Plant Invaders Atlas (SAPIA); and local, regional or global online
4 inventories (e.g. Atlas of living Australia (www.ala.org.au), Calflora (www.calflora.org), Centre for invasive
5 species and ecosystem health (www.invasive.org), Delivering Alien Invasive Species Inventories for Europe
6 (www.europe-aliens.org), and the Global Invasive Species Database (www.iucngisd.org). Searches were
7 prompted using key terms such as “pteridophyte” OR “ferns” AND “alien” OR “invasive” OR “adventive” OR
8 “naturalised” OR “non-native”. Synonyms among records in our inventory were removed and only species
9 recognised (or considered ‘unresolved’) by The Plant List (www.theplantlist.org) were retained.
10
11
12

13
14 Species invasion status terminology has often been loosely applied in the invasion literature (Blackburn 2011).
15 Therefore, to ensure consistency, we evaluated the accuracy and potentially modified the status of each species
16 according to the criteria of Falk-Peterson et al. (2006) and Blackburn et al. (2011). Not all records supplied
17 comprehensive and current information, hence, some species’ status may differ to that which was specified by the
18 source. For each species we recorded information about mode of introduction but found that horticulture was the
19 purpose for all introduced species, hence we ignored this variable in further analysis. We recorded the kingdom(s)
20 and floristic region(s) from which a species was donated, and floristic region(s) to which it was introduced
21 (kingdoms and regions follow Takhtajan 1986).
22
23
24
25
26

27 To gain an understanding of the geographic distribution of alien ferns, we assessed the frequency distribution of
28 alien species in terms of their native floristic regions and introduced floristic regions. We also collected
29 information on several ecological and biological attributes (Table 1) for each species using scientific literature,
30 online databases, field identification guides, compendiums, and open source websites (Supplementary 1). In
31 similar studies it is common practice to control for phylogenetic constraints (Grotkopp and Rejmánek 2007,
32 Moodley et al. 2016, Pyšek and Richardson 2008). However, phylogenetic relationships among existing and fossil
33 pteridophytes remain largely unresolved (Hennequin 2017, Wolf 1998) and is further constrained by the lack of
34 information surrounding primitive or advanced character states (Roux 2001). To assess the prevalence of alien
35 fern species in relation to family size we calculated for each family the proportion of the total number of accepted
36 species in that family (according to The Plant List) that have been introduced outside their native range. To assess
37 whether alien species are overrepresented in certain families we then compared the proportion of each family that
38 is alien to the proportion that is alien for Pteridophyta as a whole.
39
40
41
42
43
44
45

46 *Analysis of traits influencing invasiveness*

47
48

49 We used generalised linear models (GLMs) with binomial response variables to assess which traits (i.e.
50 explanatory variables, Table 1) are associated with invasion status (i.e. response variables; hereafter referred to
51 as ‘status’). The modelled logistic function predicts the probability of changing status for a given set of traits.
52 Since the relative importance of traits affecting invasiveness differs amongst the stages of invasion (Richardson
53 & Pyšek 2012), we estimated the status change from (i) introduced to naturalised (transition one), (ii)
54 naturalised to invasive (transition two), or (iii) introduced to invasive (transition three), with each transition
55 coded as a binary response variable. The first transition along the introduction-naturalisation-invasion
56 continuum (Richardson et al. 2000) could not be assessed as all native (i.e. non-alien) pteridophytes could not
57
58
59
60
61
62
63
64
65

1 considered in this study given the size of the taxon. Instead we included transition three (introduced to invasive)
2 in order to augment the size of the dataset for analysis of traits contributing to invasiveness.
3

4 Table 1. Explanatory variables and interactions considered in the assessment of traits potentially associated with
5 invasiveness in alien ferns
6

7
8 [Insert Table 1]
9

10 Prior to running the GLMs, we tested for collinearity between explanatory variables using Pearson's correlation
11 coefficient (Supplementary 2). We used $r=0.6$ as the cut-off point to jointly include variables in a model (Dall
12 2000). Number of native regions and number of native kingdoms were highly correlated. We first included number
13 of native regions (and not number of native kingdoms) in our models as it has often been a significant predictor
14 in similar studies (Moodley et al. 2013, 2016). However, number of native regions never contributed significantly,
15 hence we rather retained number of native kingdoms.
16
17

18 We used the output of the analysis of variance (ANOVA) to re-order the variables and relationships within the
19 models from most significant to least significant. A manual backwards stepwise selection procedure was used to
20 gradually remove the non-significant ($P>0.05$) variables, starting with the interaction terms. Variables and
21 significant interactions were kept in the model even if they showed nonsignificant single effects. In such models,
22 the order of the explanatory variables can have consequences on the remaining deviance explained by subsequent
23 variables, hence their significance. Therefore, building several models and reordering variables enables robust
24 conclusions. This also enabled us to test for the effect of variables that could be masked by partial correlation (i.e.
25 weak collinearity). Furthermore, other studies have shown that, building hierarchical models allows for testing
26 specific variables (Moodley et al. 2016; Pyšek et al. 2017). In our case, we forced residence time and number of
27 introduced regions to be in our initial models as they have shown to have significant effects in previous studies
28 (Wilson et al. 2007; Moodley et al. 2016). Ultimately, we fitted a logistic regression model using the backwards
29 manual stepwise procedure to four potential initial models.
30
31

32 To further test the robustness of our results, the same process was then repeated using a manual forward stepwise
33 selection procedure, and the function 'stepAIC' from package 'MASS' (Venables and Ripley 2002) and using
34 both a backward and forward procedure. This ensured that no variables potentially explaining deviance were
35 missed in the manual backwards selection procedure. The variables identified in these procedures were consistent
36 across models and therefore, for simplicity and ease of discussion, we only presented the results of the manual
37 backwards procedure. Since we aimed to build a usable (i.e. simple) predictive model, we selected the models
38 with a high explanatory power but with the least number of significant variables necessary to explain the
39 probability of becoming naturalised or invasive. A model that is more biologically comprehensive and
40 information-laden is likely to explain a greater proportion of the deviance but would be constrained by the
41 availability of information on various species. To assess the predictive power of the final selected models we
42 considered McFadden's R squared values for logistic regression. The final model was used to calculate and plot
43 the probability of an alien fern becoming naturalised or invasive. All analyses were conducted with the open
44 source R software (version 1.1.383) (R Development Core Team 2017).

Inventory, geographic distribution, and family representation

1
2 The inventory comprised 157 species of alien ferns (Supplementary 1), which is ca. 0.02% of the 10 620
3 recognised species of ferns. In terms of invasion status, 12% of the recorded species were introduced but not
4 naturalised, 49% were naturalised but not invasive, and 39% were invasive. Geographic distribution of donated
5 and received fern species at the scale of floristic kingdoms suggests little latitudinal constraint (Fig. 1). At the
6 scale of floristic regions (FR) some patterns were evident. The Eastern Asiatic (FR 2) and Irano-Turanian (FR 8)
7 donated the greatest numbers of species whereas few species originated from the Mediterranean (FR 6), Indian
8 (FR 16), and the Indochinese (FR 17). Regions which received the most species were the Neozeylandic (FR 35),
9 Hawaiian (FR 21), and Circumboreal (FR 1), and although FRs 2 and 8 donated many species, they received few
10 species. Specific species of concern that were shown to be invasive over extensive introduced ranges include
11 *Lygodium japonicum* (Thunb.) Sw., *Lygodium microphyllum* (Cav.) R. Br., *Adiantum raddianum* C. Presl,
12 *Angiopteris evecta* (G. Forst) Hoffm, *Cyrtomium falcatum* (L. f.) C. Presl, *Macrothelypteris torresiana* (Gaudich.)
13 Ching., *Nephrolepis cordifolia* (L.) C. Presl, *Phlebodium aureum* (L.) J. Sm., *Pityrogramma calomelanos* (L.)
14 Link, *Pteris vittata* L., and *Sphaeropteris cooperi* (F. Muell.) R.M. Tryon.

22 [Insert Figure 1]

25 **Fig. 1** Numbers of alien fern species donated by native floristic regions (grey circles) and received by
26 introduced floristic regions (black circles). The 35 floristic regions of the world fall into 6 floristic kingdoms
27 (based on Takhtajan (1986)). The size of the circle corresponds to number of species

30 Twenty-four families were represented by alien fern species. Alien species comprised 0.02% of all recognised
31 fern species. Families within which alien species were overrepresented relative to their size included the
32 Psilotaceae, Nephrolepidaceae, Equisetaceae, Onocleaceae and Lygodiaceae (Fig. 2). In terms of absolute
33 numbers of alien species contributed, Pteridaceae (37 species), Dryopteridaceae (21 species), Blechnaceae (12
34 species), Polypodiaceae (11 species), and Dennstaedtiaceae (11 species) ranked the highest (Fig. 2).

39 [Insert Figure 2]

41 **Fig. 2** The prevalence of alien fern species in relation to family size (number of species), calculated as the
42 proportion of the total number of species that are alien within each family, as well as for Pteridophyta as a whole
43 (respectively)

Traits influencing invasiveness

48 The final model for the transition from introduced to naturalised (transition one) retained the variables mode of
49 regeneration and number of introduced regions; for the transition from naturalised to invasive (transition two),
50 number of introduced regions, light, life form, and disturbed habitat; and for the transition from introduced to
51 invasive (transition three), number of introduced regions, light, disturbed habitat, number of native kingdoms, and
52 mode of regeneration (Table 2; Fig. 3). Growth form, wet habitat, and residence time had no significant effect.
53 The McFadden's R squared values for logistic regression showed the variation explained by our models to be 30
54 % for transition one, 30% for transition two, 40% for transition three.

1 Number of introduced regions significantly increased probability of species becoming naturalised or invasive. The
2 ability to regenerate both sexually and vegetatively significantly increased the likelihood of changing from the
3 ‘introduced’ status (transitions one and three) but had no effect on becoming invasive once naturalised (transition
4 two). Similarly, disturbed habitats also promoted transitions from ‘introduced’ to other statuses, though marginally
5 for transition two. Species with the ability to survive all types of light conditions or with a preference for full sun,
6 had a higher probability to transition to “invasive” (transitions two and three) than shade tolerant species.
7 Geophytes proved more likely to become invasive than epiphytes or lithophytes. Number of native kingdoms (our
8 best available proxy for environmental tolerance) increased the likelihood to become invasive (transition three).

10
11

12 [Insert Table 2]

13 [Insert Figure 3]

14 15 16 17 18 **Discussion**

19 *Family and geographic representation*

20 Our global inventory of alien ferns showed that there are significantly more alien species (157) than the ca. 60
21 species noted by Robinson et al. (2010). An estimated 3.9% of the global vascular flora have naturalised or become
22 invasive (van Kleunen et al. 2015) which is a significantly higher proportion than what we found for terrestrial
23 ferns (0.02% are alien of which half have naturalised or become invasive). However, due to the poor recording of
24 pteridophytes and their invasion status in inventories, there are likely to be more alien fern species than we
25 recorded. In fact, a fern is likely to be noted only once it has become an established and ecologically damaging
26 invader (Amoroso 2003), which likely explains the underrepresentation of introduced species in our study
27
28
29
30
31
32

33 Similar studies screening for invasiveness identified a strong relationship between invasion status and the extent
34 of the species’ native and introduced ranges (Rejmanek and Richardson 1996; Pyšek et al. 2009; Moodley et al.
35 2013; Moodley et al. 2016; Latombe et al. 2017). Similarly, in our study number of introduced regions had a
36 significant effect on species at each stage of transition, and species with a higher number of native kingdoms
37 showed a greater probability of becoming invasive than those with a smaller native range. In general, climate,
38 species specific ecological requirements, ease of dispersal and the availability of suitable habitat largely determine
39 the distribution of fern species (Lester et al. 2009). In our study however, the geographical distribution of donated
40 and received species (Fig.1) appears to have been determined largely by anthropogenic influences as no particular
41 longitudinal patterns are evident. Furthermore, all species were introduced for horticultural purposes. Floristic
42 regions with large numbers of donated or received fern species typically had (i) an overrepresentation of alien or
43 invasive plants generally (e.g. on islands such as England, New Zealand and Hawaii; Vernon and Ranker 2013);
44 (ii) well-studied alien fern invasions (e.g. Hawaii, FR 21; Wilson 2002); (iii) many native fern species with
45 horticultural value (e.g. Southeast Asia, FR 2 and 8; Amoroso 2003); and (iv) long histories of horticultural
46 introductions (e.g. Britain, FR 1; Smith 1895).

53
54
55

56 Ferns are selected in horticulture for their full foliage appearance, compact size, evergreen habit, unique
57 characteristics (colour, texture or shape), high reproductive ability, fast growth rate, and high environmental
58 tolerance (Amoroso 2003). Plant traits that are popular in horticulture often facilitate the invasiveness of a species
59
60
61
62
63
64
65

1 (Dehnen-Schmutz et al. 2007). In our inventory of alien ferns, families within which aliens were overrepresented
2 often had species that were invasive over extensive introduced ranges and were popular in horticulture (Fig. 2;
3 Supplementary1). The recorded families generally concur with those suggested by horticultural plant guides, e.g.
4 Young (1996) listed species from the families Pteridaceae, Blechnaceae, Davalliaceae, Dennstaedtiaceae,
5 Nephrolepidaceae, and Lygodiaceae; and species such as *Lygodium japonicum* (Thunb.) Sw., *Lygodium*
6 *microphyllum* (Cav.) R. Br., *Angiopteris evecta* (G. Forst) Hoffm., *Pteris vittata* L., and *Sphaeropteris cooperi*
7 (F. Muell.) R.M. Tryon. were identified as species of concern in our study but have also previously been identified
8 as serious invaders (Robinson et al. 2010).
9

10
11
12 Our study supports the notion that progression along the introduction-naturalisation-invasion continuum is
13 mediated by stage-dependant traits (Richardson and Pyšek 2012; Moodley 2016). The general likelihood of an
14 alien fern species to become naturalised or invasive once introduced was high (Fig. 3) compared to what is known
15 for other taxa (Williamson and Fitter 1996). Alien ferns have an 80% chance of becoming naturalised if they
16 possess the ability to regenerate both sexually and vegetatively. Mode of regeneration is often a significant
17 predictor of invasive success in various species (Kolar and Lodge 2001) but is not necessarily a consistent
18 predictor across all taxa. In Proteaceae, invasiveness was related to regeneration mode where resprouters were
19 more likely to naturalise while reseeders were more likely to invade (Moodley et al. 2013), but no relationship
20 was evident in Araceae (Moodley et al. 2016). The combination of multiple reproductive modes and the ability to
21 occupy sun-exposed sites are dual traits shared by many invasive fern species (Robinson et al. 2010; Arosa et al.
22 2012). Higher light conditions/ availability can enable faster growth rates which in turn should increase
23 invasiveness, whereas shaded environments can limit the spread of various fern species (Mehltreter and Sharpe
24 2013). Accordingly, the ability to survive under all light forms or high light conditions (e.g. the highly invasive
25 *Angiopteris evecta* (G. Forst.) in Hawaii, Christenhusz 2008) increased the probability of alien ferns becoming
26 invasive, whereas strictly shade-loving species held a lower potential for invasiveness. Furthermore, ferns that
27 have characteristics which allow them to survive in habitats of low nutrients and high-light conditions are best
28 adapted to grow in disturbed areas (Walker and Sharpe 2010).
29
30

33
34
35
36
37
38
39
40

41 Disturbance, especially those caused by human activities (e.g. landslides, cliffs, roads and railways, fire regimes,
42 and plantations) commonly promotes the spread and proliferation of invasive plants and generally reduces
43 resistance to invasion by intact native communities (Richardson et al. 2011; Baard and Kraaij 2014; Terzano et
44 al. 2018; Hobbs and Huenneke 1992). In our study disturbance facilitated the transition from naturalised to
45 invasive in alien fern species, similarly Robinson et al. (2010) and Walker and Sharpe (2010) found that
46 disturbance promoted invasive behaviour in alien ferns by increasing growth and subsequent regeneration. Ferns
47 thrive in urban environments and can establish successfully in and on manmade surfaces such as the under hangs
48 of bridges, old cracked walls, and drainage canals (Morajkar et al. 2015). In South Africa, *Sphaeropteris cooperi*
49 (F. Muell.) R.M. Tryon. occurs in higher densities in commercial timber plantations (associated with disturbance)
50 than in undisturbed indigenous forest (E Jones, unpublished data).
51
52
53
54
55
56

57 We found that ferns with a geophytic life form, rather than epiphytic or lithophytic, were more likely to become
58 invasive. Similarly, geophytic ferns accounted for most of the invasive fern species recorded in Hawaii, whereas
59
60
61
62
63
64
65

1 very few were epiphytic (Robinson et al. 2010; Wilson 2002). In contrast to geophytes, epiphytes are generally
2 limited by the availability of the particular surfaces on which they grow and are more likely to be exposed to water
3 stress because they are rooted in shallower substrates (Mehltreter and Sharpe 2013). However, exceptions do exist,
4 for instance *Platyserium bifurcatum* (Cav.) C. Chr. grows in large colonies in its native (Pemberton 2003) and
5 invaded (EJJ pers. obs.) habitat, where it is able to form extensive chains within a single tree and commonly
6 spreads to trees adjacent to the parent population. Just as certain geophytic species may depend on particular soil
7 characteristics, so too do epiphytic and lithophytic species depend on the particular characteristics of their host
8 substrate (Mehltreter et al 2010) therefore a greater understanding of how environmental factors influence richness
9 amongst fern life forms is needed (Richardson and Walker, 2010).

10
11
12
13
14 Propagule pressure is another significant predictor of invasiveness in various plant taxa (Colautti 2006) and
15 involves the number of reproductive propagules and the rate at which they arrive in an area per unit time
16 (Williamson 1996; Simberloff 2009). Some studies screening for invasiveness used several measures as a proxy
17 for propagule pressure, one of which is the number of introduced regions (Colautti et al. 2006; Zenni and
18 Simberloff 2013; Moodley et al. 2016). Although introductions of a species across numerous floristic regions may
19 in some cases concur with extensive introduction efforts within a region (and as such serve as a proxy for
20 propagule pressure), this relation cannot be assumed, particularly at the scale of global floristic regions. We argued
21 that the introduction of a species within one floristic region cannot facilitate invasion of that species in another
22 floristic region and rather interpreted number of introduced regions, and number of native kingdoms (at yet a
23 larger spatial scale), as proxies for environmental tolerance (cf. Denehen-Schmutz et al. 2007). In our study, a
24 larger number of native kingdoms significantly promoted the transition to invasive suggesting that high
25 environmental tolerance in ferns increases their invasive potential.

26
27
28
29
30
31
32
33 Additional factors that could not be assessed in this study include aspects such as such as leaf life span (Mehltreter
34 and Sharpe 2013), frond size, plant size, growth rate, spore load and longevity (Durand and Goldstein 2001), the
35 ability to alter soil function (Chau et al. 2013), the use of chemical defence, and the presence of natural enemies
36 or predators (Robinson et al. 2010). These traits were considered in other studies on invasive ferns and are traits
37 displayed by popular horticultural species, they are likely to influence invasiveness in alien ferns and warrant
38 further investigation. Furthermore, gametophytes and sporophytes exist separately and their ecological
39 requirements for survival differ (Sharpe et al. 2010) for e.g. gametophytes of some species have been recorded as
40 being more stress tolerant (Sato and Sakai 1981) and inhabiting areas inhospitable (Peck et al. 1990) to their
41 sporophyte form. The manner in which disparate requirements of these different life stages affect species'
42 distribution ranges or their invasive potential have not yet been explored but may further explain distribution and
43 invasiveness in alien ferns (Sharpe et al. 2010).

44 45 46 47 48 49 50 51 **Conclusion**

52
53 Our model explained 30-40% of the variance associated with invasiveness in terrestrial alien ferns and highlighted
54 that a geophytic life form, reproductive plasticity, tolerance for disturbance and varied light conditions, and a
55 broad introduced range (hence a high environmental tolerance and popularity in horticulture) are important
56 determinants of invasiveness. Furthermore, our study supported that there are invasion-stage dependant effects,
57 whereby a trait or set of traits becomes important during different invasion stages (Pyšek et al. 2009). We found
58
59
60
61
62
63
64
65

1 that some mechanisms driving invasiveness in alien ferns are similar to those in other taxa, e.g. thriving under
2 high light conditions and disturbance (Richardson and Pyšek 2012). Horticulture is a well-documented driver of
3 invasiveness in various alien species (Dehnen-Schmutz et al. 2007) and appeared to have been highly influential
4 in the spread and successful establishment of alien ferns, supported by the significant influence of number of
5 introduced regions as a predictive variable. Terrestrial ferns have to date been largely overlooked as a likely
6 invasive taxon, but this study showed that some ferns have high invasive potential. We identified additional
7 biological traits of ferns that may influence invasiveness and warrant further study. Divergent ecological
8 requirements and tolerances of the two life stages (gametophyte and sporophyte) of ferns may be of particular
9 importance in their invasion success. In conclusion, this study initiated the identification of traits associated with
10 invasiveness in ferns and highlighted aspects that require further investigation.

Fig. 1 Numbers of alien fern species donated by native floristic regions (grey circles) and received by introduced floristic regions (black circles). The 35 floristic regions of the world fall into 6 floristic kingdoms (based on Takhtajan (1986)). The size of the circle corresponds to number of species

Fig. 2 The prevalence of alien fern species in relation to family size (number of species), calculated as the proportion of the total number of species that are alien within each family, as well as for Pteridophyta as a whole (respectively)

Fig. 3 The relative probability of an alien fern species transitioning from (a) introduced to naturalised (transition one), (b–d) naturalised to invasive (transition two), or (e–h) introduced to invasive (transition three) for significant variables (details in Table 1) in relation to the effect of number of introduced regions as it was always significant. We fixed model variables not displayed in each graph to their intercept values to better describe the relative probabilities associated with the variations of the variable displayed in addition to number of introduced regions. For binary variables, 1's and 0's follow the descriptions provided in Table 1.

Table 1. Explanatory variables and interactions considered in the assessment of traits potentially associated with invasiveness in alien ferns

Trait	Variable type	No. of modalities	Explanation
Mode of regeneration	Categorical	2	(1) Adopts both methods of reproduction (vegetative and sexual) / (0) only adopts one method (<u>vegetative or sexual</u>)
Life form	Categorical	2	(1) Geophytic (soil substrate) / (0) epiphytic (arboreal substrate) or lithophytic (rock or stone substrate)
Growth form	Categorical	2	(1) Rhizomal / (0) arborescent (e.g. tree fern)
Wet habitat	Categorical	2	(1) Preference for wet habitats (wetlands, streams, etc.) / (0) preference for drier habitats
Disturbed habitat	Categorical	2	(1) Preference for disturbed habitats (e.g. roadsides or plantation) / (0) preference for undisturbed habitat
Light	Categorical	4	Species occurs primarily in: full sun / full shade / semi-shade / all light forms
Number of native regions (proxy for environmental tolerance)	Continuous		A count of native floristic regions (based on Takhtajan 1886)
Number of native kingdoms (proxy for environmental tolerance)	Continuous		A count of native kingdoms (based on Takhtajan 1886)
Number of introduced regions (proxy for popularity in horticulture)	Continuous		A count of introduced floristic regions (based on Takhtajan 1886)
Residence time	Continuous		Years (calculated as the time elapsed between the earliest recorded year in the introduced region or earliest year of publication and the year 2017)
Disturbed habitat × light	Interaction		To determine if light availability influences a fern's occurrence in disturbed habitat)
Number of introduced regions × life form	Interaction		To consider the types of life forms that are more widely introduced (~ popularity in horticulture)
Mode of regeneration × wet habitat	Interaction		To consider the importance of water in fern reproduction

Table 2. Variables retained by stepwise backwards logistic regression ($P < 0.10$) for significantly influencing the probability of an alien fern species to transition from introduced to naturalised (transition one), naturalised to invasive (transition two), or introduced to invasive (transition three)

	Dev	<i>P</i> value	Estimate	SE
<i>Transition one</i>				
Intercept			0.041	0.768
Mode of regeneration ^a	7.556	0.006 **	1.803	0.704
Number of introduced regions	2.911	0.088 .	0.627	0.571
<i>Transition two</i>				
Intercept			-4.648	1.647
Number of introduced regions	19.875	8.267e-06 ***	0.320	0.105
Light ^b	12.250	0.007 **	All: 2.596	0.970
			Semi-shade: 0.838	0.852
			Sun: 1.057	0.963
Life form ^c	3.579	0.059 .	2.410	1.386
Disturbed habitat ^d	3.091	0.079 .	0.771	0.439
<i>Transition three</i>				
Intercept			-4.450	1.160
Number of introduced regions	18.956	1.337e-05 ***	0.305	0.108
Light ^b	12.678	0.005 **	All: 2.912	1.051
			Semi-shade: 1.273	0.974
			Sun: 1.910	1.080
Disturbed habitat ^d	3.885	0.049 *	0.929	0.465
Number of native kingdoms	4.048	0.044 *	0.435	0.236
Mode of regeneration ^a	4.399	0.036 *	0.947	0.465

^aThe reference level included in the intercept is sexual or vegetative reproduction only; the estimate displayed is for a species displaying both modes of regeneration.

^bThe reference level included in the intercept is shade; the estimate displayed is for all types of light, semi-shade and sun.

^c The reference level included in the intercept is epiphyte or lithophyte; the estimate displayed is for geophytic species.

^d The reference level included in the intercept is for a species showing preference for undisturbed habitat; the estimate displayed is for a species showing preference for disturbed habitat.
