Abstract

Exploring a catalytic reaction, other than water oxidation, at the photoanode of a photoelectrochemical cell is probably a key feature to more efficiently generate the electrons needed to produce solar fuels. In this framework, we describe herein the fabrication of a TiO₂

based DSPEC using a zinc porphyrin (ZnP) sensitizer and a TEMPO organo-catalyst that quite efficiently catalyzes light driven oxidation of methoxybenzyl alcohol into aldehyde. Two dyads ZnP-TEMPO, differing by the anchoring group (carboxylic acid and hydroxamic acid) on ZnP, were prepared and their electrochemical, absorption, emission properties were recorded and quantum chemical modelling was realized. The photovoltaic performances in DSSCs were first examined in order to optimize the dyeing conditions and compare the relative efficiencies of the compounds. The dyads substituted with TEMPO outperform the reference zinc porphyrin lacking TEMPO with a much higher J_{sc} and V_{oc} . The photocatalytic properties after immobilization on TiO_2 nanocrystalline films towards *para*-methoxy benzyl alcohol oxidation were explored in borate buffer and in acetonitrile electrolyte. In borate buffer, the optimal pH was 8 and using the dyad ZnP-TEMPO anchored with hydroxamic acid, *para*-methoxy benzaldehyde was selectively produced with average photocurrent density of $200 \mu A/cm^2$, a faradaic efficiency of 82%, a TON of 26, and a TOF of $47 h^{-1}$. In acetonitrile in presence of 0.1 M of N-methyl-imidazole, the same dyad gives an average photocurrent density of about $100 \mu A/cm^2$, a faradaic efficiency of 76%, a TON of 13, and a TOF of $24 h^{-1}$. The stability of the anchor is crucial in acetonitrile electrolyte, where the dyad is quite soluble, since only the dyad functionalized with hydroxamic acid is compatible with these organic solvent conditions. Overall this study paves the way to the development of more efficient and probably more stable TiO_2 based DSPECs for alcohol oxidation that could advantageously complement those devoted to water oxidation.

Introduction

Degradation of the biosphere by the pollution generated from fossil fuels burning has stimulated an intense research activity devoted to the storage of sunlight as chemical fuels towards a sustainable society.^{1,2,3} To this end, the development of photoelectrochemical cell (PEC) is one of the most investigated and probably the most promising approach.⁴⁻⁶ In such systems, a compound is reduced at the photocathode by the electrons produced by the oxidation of a substrate at the photoanode. In many cases, water is the source of electrons upon its oxidation into oxygen. Although this reaction is interesting because water is a very abundant and harmless compound, it is a challenging transformation since it involves four oxidizing equivalents. Moreover, it is energetically costing as it requires a potential of 1.23 V vs. NHE at pH = 0 and it is usually catalyzed by expensive noble metal based catalysts.^{7,8} All these factors taken together explain why water oxidation is most often the limiting process that decreases the overall efficiency of PECs. Water oxidation releases oxygen, which is a product of poor economic value, but they are several attractive alternative reactions that can produce more added values products.⁹⁻¹¹ For example, replacement of water oxidation by the selective oxidation of organic molecules, such as alcohols, is certainly a valuable strategy to produce high-valued carbonyl compounds, and at the same time it is possible to reduce various substrates such as protons, carbon dioxide or nitrogen at the other electrode in a tandem system.¹²⁻¹⁴ Besides generating more economically valuable materials at both electrodes, the advantages of alcohol oxidation stems from the fact that this reaction necessitates a lower potential than water oxidation ($-0.143 V$ vs. NHE for benzyl alcohol

oxidation *versus* 1.23 V vs. NHE for water oxidation at pH = 0 for both)¹⁵ and only two holes instead of four, and consequently only two photons. In addition, light driven alcohol oxidation could represent an attractive, cheaper, safer and more environmentally benign oxidation protocol than the usual noxious chemical approaches that employ stoichiometric amounts of toxic oxidants.¹⁶ Moreover, biomass remains a largely unexploited supply of raw materials for the chemical industry and is indeed an immense source of alcohols.¹⁷ There are several approaches to design a PEC and among them dye-sensitized photoelectrosynthesis cell (DSPEC) is particularly interesting, because it does not involve low bandgap semiconductors, which present the disadvantage of being usually unstable in contact with an aqueous electrolyte upon light irradiation.¹⁸ On the other hand, the performances of DSPECs are usually modest, most certainly because the dye must feed the catalyst with several redox equivalents before catalysis occurs.¹⁹⁻²² This requirement is particularly demanding in the context of a photosensitized electrode, because it implies that: i) the dye photoexcitation frequency is high, so that the same dye absorbs photons at close intervals in order to funnel several charges to the catalyst before charge recombination takes place, which is a difficult task with the low photon flux of sunlight, or ii) the lateral charge diffusion inside the monolayer of the chemisorbed molecules is quite efficient, at least faster than charge recombination, so as several different oxidized dyes could feed the catalyst with oxidation equivalents.²³⁻²⁷ As a result, choosing an oxidation reaction which involves only two oxidizing equivalents, instead of four, could be a nice opportunity to alleviate the challenging multiple charge accumulation step in DSPEC. On this field, the seminal work of Meyer and co-workers²⁸ was followed by a few other studies,^{19, 29, 30} but alcohol oxidation in DSPEC still remains an unexplored scientific topic today, particularly if one compares it with water oxidation.^{31, 32} All the previously reported studies of alcohol oxidation with DSPEC that we are aware of rely on a ruthenium polypyridine complex as catalyst^{19, 28, 31, 32} and very often with a ruthenium tris-bipyridine based TiO₂ sensitizer, although a few publications describe systems with an organic sensitizer.^{29, 30, 33, 34} Very recently, an interesting study reports a DSPEC type photoanode made of TiO₂ film sensitized by a ruthenium tris-bipyridine complex that depolymerizes lignin with N-hydroxyphthalimide catalyst solubilized into an acetonitrile based electrolyte.³⁵ A catalytic photocurrent density of about 130 $\mu\text{A}/\text{cm}^2$ was measured upon light irradiation (200 mW/cm^2) with an applied potential of 0.75 V vs. SCE. Nitroxides in general and 2,2,6,6-tetramethyl-1-piperidine N-oxyl (TEMPO) in particular are very active, cheap and green catalysts for alcohol oxidation,³⁶ that is even applied to chemical industry.^{37, 38} Light driven alcohol oxidation catalyzed by a TEMPO derivative has been demonstrated in homogeneous systems with a dye in presence of a sacrificial electron acceptor (typically Co(NH₃)₅Cl₃).³⁹⁻⁴³ TEMPO mediated alcohol oxidation was also described with a visible light absorbing n-type semiconductor such as BiVO₄ or WO₃ as photoanode.^{14, 44-46} Interestingly, TEMPO derivatives were successfully implemented as redox mediators in dye sensitized solar cells proving that hole transfer could be efficiently realized from an oxidized sensitizer to the nitroxide radical even with a weak driving force.⁴⁷⁻⁵⁰ Moreover, visible light photocatalytic TEMPO-mediated oxidation of alcohols to aldehydes has been reported with dyes upon oxidative quenching by a sacrificial electron acceptor in solution or with a hybrid system consisting of TiO₂ or ZnO dye-sensitized nanoparticles.^{39, 40, 42, 43}

In this study, we investigate the fabrication of a TiO₂ based DSPEC for alcohol oxidation using for the first time a TEMPO catalyst covalently appended to an organic sensitizer (Figure 1). The purposes of this study are two folds. First, to explore the benefit of choosing a two holes oxidation reaction by comparing its efficiency with other reported DSPECs oxidizing water instead of alcohol. Second, to investigate the possibility of designing DSPEC with only abundant elements by replacing the classical ruthenium alcohol oxidation catalyst⁵¹ by a TEMPO derivative and to assess its potential in term of photocatalytic performance. Towards this objective, two dyads composed of a zinc porphyrin linked to a TEMPO were prepared and their photocatalytic properties in DSPECs investigated. Zinc porphyrin sensitizers were successfully used in DSPEC for water oxidation,⁵²⁻⁵⁶ legitimating such choice since the catalytic potential of TEMPO is less anodic than that of many water oxidation catalysts. Hydroxamic acid was selected as anchoring group in order to maintain a robust linkage to the TiO₂ surface and avoid leaching of the dyad during photocatalysis.⁵⁷⁻⁶¹ Indeed, oxidation catalysis occurs more favorably in neutral and even basic conditions,^{62, 63} in such conditions it is crucial to install a strong anchoring group to avoid premature desorption of the molecular system.

Figure 1. Structures of the compounds used in this study.

Overall, this study highlights that alcohol oxidation in DSPEC with TEMPO organo-catalyst activated by an organic dye is a promising and valuable strategy to replace classical water oxidation, since quite good efficiency could be demonstrated with ZnP-TEMPO dyads. The system works both in aqueous and organic solvents and the covalent attachment of the catalyst to the dye is not absolutely mandatory to achieve good photocatalytic performances, but it presents the real advantage of providing an easier recovery of the catalyst and becomes unavoidable when the catalyst is insoluble in the electrolyte.

Results and discussion

Synthesis

The synthetic approach for the preparation of the porphyrin dyads ZnP-TEMPO is illustrated in Scheme S1. Initially the **HO₂C-ZnP-CO₂H** porphyrin was synthesized according to the literature⁶⁴ and then an amide coupling with NH₂-TEMPO was conducted using HATU as coupling reagent, yielding the **HO₂C-ZnP-TEMPO** dyad. Subsequently, the carboxylic acid anchoring group was converted into hydroxamic acid by using hydroxylamine hydrochloride, affording the **hyd-ZnP-TEMPO** dyad. The synthetic procedure of the reference derivative **HO₂C-ZnP** has been previously reported from our group,³⁴ while the reference compound **hyd-ZnP** was prepared following similar reactions (Scheme S2). The successful synthesis of all the final and intermediate compounds was verified *via* ¹H and ¹³C NMR spectroscopies (Figures S26–S34, ESI[†]), and MALDI-TOF mass spectrometry. The assignment of the corresponding peaks was achieved through 2-D COSY, HMBC and HSQC NMR spectra analysis.

Absorption and emission spectra

The absorption spectra of the compounds were recorded in solution (Figures S1-S4) and on thin TiO₂ films (Figure S5). The spectroscopic data are collected in Table 1. The spectra display the classical absorption bands of tetraaryl zinc porphyrin with a Soret transition located at 426 nm and two Q transitions peaking at 555 and 598 nm. As expected, the appended TEMPO moiety does not alter the absorption spectra of the ZnP-TEMPO dyads, since there is no electronic communication between ZnP and TEMPO owing to the absence of a π -conjugated pathway (see also calculations below). Interestingly, both the reference zinc porphyrins and ZnP-TEMPO dyads are emissive with no significant extinction of the fluorescence in the dyads, indicating that TEMPO does not quench the porphyrin singlet excited state by electron transfer nor promotes intersystem crossing (Figures S6-S7).

Electrochemistry

The redox potentials of the zinc porphyrin and TEMPO were investigated by cyclic voltammetry after chemisorption on mesoporous indium tin oxide (meso-ITO) in acetonitrile containing lithium perchlorate (0.1 M) as supporting electrolyte (Figures S8-S9). The two oxidation processes are quite close and consequently are not well separated in the cyclic voltammograms. However, it is clear that zinc porphyrin oxidation occurs at about 100 mV higher potential than that of TEMPO, leaving a modest, but non null, driving force for the hole shift reaction from oxidized zinc porphyrin to TEMPO ($^+\text{ZnP-TEMPO} \rightarrow \text{ZnP-TEMPO}^+$). Efficient electron transfer from TEMPO to an oxidized sensitizer on TiO₂ with a small Gibbs free energy (-0.18 eV) was reported, illustrating that such process can occur with weak driving force.⁴⁷ On the other hand, the electron injection reaction is thermodynamically favorable by at least -0.37 eV in borate buffer at pH = 8 (Table 1). Upon addition of *para*-methoxybenzyl alcohol (MeO-Ph-CH₂OH) in acetonitrile electrolyte, the cyclic voltammogram of the dyad ZnP-TEMPO on *meso*-ITO shows the appearance of an intense irreversible wave attributed to the catalytic oxidation of alcohol by TEMPO, with an onset potential at 0.74 V vs. SCE (Figure S10).

Quantum chemical calculations

We have performed DFT calculations on **hyd-ZnP-TEMPO** (see the ESI[†] for technical details). First, the calculations confirmed that the unpaired electron is confined on the **TEMPO** and that vertical oxidation yield a change of density localized on that unit specifically, the saturated bridge preventing delocalization between the two moieties (Figure S11). Second the MO diagrams of **hyd-ZnP-TEMPO** (Figure S12) reveals that the unpaired electron of the **TEMPO** appears slightly below the HOMO located on the **ZnP** unit. The computed difference is -0.21 eV, hinting at a small driving force for the hole shift, one **hyd-**

ZnP-TEMPO is oxidized, which is consistent with the experimental findings. To have a more accurate evaluation of this energy difference (than with MOs), we have determined the adiabatic ionization potentials (including zero-point corrections) for the separated **ZnP** and **TEMPO** moieties by the Δ SCF approach. The computed IP are 5.08 and 5.21 eV for **ZnP** and **TEMPO**, respectively, leading to a driving force of -0.13 eV well in line with the electrochemical measurements.

Photophysical study

Electronic transient absorption (TA) measurements were performed with both **hyd-ZnP-TEMPO** and the reference **hyd-ZnP** dye onto TiO₂ films in the borate electrolyte. A first series of fs-ps measurements were carried out upon 550 nm excitation of films with an absorbance of about 0.4 at that wavelength (Figure 2A). Owing to the very high absorbance of the film in the Soret band region, no TA could be measured between 450 and 400 nm. Directly after excitation, the TA spectra exhibit an intense excited-state absorption (ESA) band around 460 nm that can be attributed to the local S₁ state of ZnP. ESA is also observed above 590 nm and is modulated by the overlapping negative contributions from the ground-state bleach (GSB) at 600 nm as well as the stimulated emission (SE) around 610 and 660 nm. The 460 nm band loses about 80% of its intensity within 100 ps and the contribution of the SE at 670 nm decays as well. Subsequently, the 620-750 nm region is dominated by a broad ESA. Unambiguous assignment this ESA is difficult, because the radical cation, anion and the T₁ state of ZnP are known to absorb in this region.^{67, 68} However, the changes in the TA spectra are consistent with the formation of the radical cation of the ZnP subunit upon charge injection into TiO₂. Unambiguous detection of ZnP cation was achieved with a second series of fs-ps TA measurements with low concentration of adsorbed dyes (absorbance of ~0.05 at 550 nm) to allow for monitoring the Soret band region. Figure 2B shows that the decay of the S₁ band at 460 nm is accompanied by a partial recovery of the GSB in the Soret region as well as by the rise of a new band at 405-410 nm. The latter can be unambiguously assigned to the radical cation of ZnP.^{69, 70} This feature is usually difficult to detect because of its close proximity to the intense Soret band. The time evolution of the intensity of the ZnP cation band is depicted in the inset of Figure 2B. The rise of the cation band can be well reproduced using the sum of two exponential functions with 6.3 and 75 ps time constants and similar amplitudes.

Figure 2. fs-ps transient absorption spectra recorded at various time delays after 550 nm excitation of TiO_2 films with high (A) and low (B) concentrations of adsorbed **hyd-ZnP-TEMPO**. The gray line in A represents the stimulated emission spectrum in acetonitrile. The inset in B shows the time evolution of the absorbance of the porphyrin cation band at 405 nm.

The slower cation dynamics were monitored using ns- μs TA upon 532 nm excitation. As shown in Figure 3, both the GSB and the ZnP cation bands decay concurrently on multiple timescales with 2, 50 ns and 10 μs time constants to a weak residual spectrum with >100 μs decay time. Because of the absence of spectroscopic signature of the TEMPO cation in the 370-1500 nm region, it is impossible to determine whether the decay of the ZnP cation and the recovery of the GSB are due to a hole shift from ZnP cation to TEMPO or to charge recombination with the semi-conductor. The same TA measurements, performed with the **hyd-ZnP** reference compound in TiO_2 , also evidence the formation of the ZnP cation (Figure S13). The decay of the ZnP cation band does not differ significantly from that measured with **hyd-ZnP-TEMPO** (Figure S14). However, this similarity does not exclude occurrence of hole shift to TEMPO, but could result from a slow hole shift that only partially competes with recombination. This would be consistent with the weak driving force of this process (~ 0.1 eV). By comparison, intermolecular hole shifts between TEMPO and oxidized organic dyes on TiO_2 with a driving force of 0.18 and 0.25 eV were reported to occur with 6 and 31 μs , time constants, respectively.⁴⁷ To check the feasibility of hole shift from ZnP cation to TEMPO, the radical cation of zinc tetraphenylporphyrine (ZnTPP) was generated upon bimolecular electron transfer with 0.02 M maleic anhydride as electron acceptor in acetonitrile. Figure S15A and S16 show the buildup on the hundred of nanoseconds timescale of the ZnTPP cation band in the 405-410 nm region. If 0.02 M TEMPO is additionally present in the solution, the ZnTPP cation band is totally suppressed (Figure 15B). This is a clear evidence that hole shift from ZnP cation to TEMPO is operative.

Figure 3. ns- μ s transient absorption spectra recorded at various time delays after 532 nm excitation of a TiO₂ film with a low concentration of adsorbed **hyd-ZnP-TEMPO**. The inset shows the time evolution of the absorbance of the porphyrin cation band at 410 nm.

Photovoltaic performances in dye sensitized solar cells

Although the primary goal of this study is not to develop new systems for photovoltaic cells, we were curious to assess the photovoltaic performances of these dyes in DSSC. First, it enables to screen the best dyeing conditions of the TiO₂ films. Second, an effective “dye-catalyst” for DSPEC should produce photocurrent in DSSC, therefore the photovoltaic efficiency in DSSC can provide first insights into the potential of these systems for photocatalysis. First, different soaking times were investigated from 1 hours to 8 hours and it turns out that 3 hours is the optimal condition in the toluene/ethanol (1/1) at the concentration of 0.2 mM. Then, these conditions were used to chemisorb the dyes on nanocrystalline TiO₂ electrodes that were used as photoanodes to fabricate DSSCs with iodide/triiodide redox couple in acetonitrile electrolyte (see experimental part for details). The metrics of the solar cells, such as short circuit current density (J_{sc}), open circuit voltage (V_{oc}), fill factor (ff) and power conversion efficiency (PCE) are gathered in Table 2. Typical current/voltage curves and incident photon-to-current efficiency (IPCE) spectra are shown in Figure S17 and Figure S18 respectively.

Table 2. Metrics of the solar cells recorded with the different dye under calibrated AM1.5 (100 mW/cm²) sunlight simulator.

	J_{sc} (mA/cm ²)	V_{oc} (mV)	FF (%)	PCE (%)
hyd-ZnP	1.82±0.08	573±3	69±1	0.72±0.01
hyd-ZnP-TEMPO	3.45±0.2	632±5	72±1	1.65±0.05

HO₂C-ZnP	1.77±0.2	570±2	69±2	0.70±0.02
HO₂C-ZnP-TEMPO	4.3±0.4	645±10	72±2	2.00±0.2

First, the PCEs of these porphyrin systems are indeed much lower than those of the champion push-pull porphyrin sensitizers, which reach PCEs around 13-14%.^{71, 72} Compared with previously reported similar simple tetraryl zinc porphyrins,⁷³ the dyes of this study display lower PCEs essentially due to their lower J_{sc}, although one publication from Diau and co-workers⁷⁴ reports similar performances as ours. It is likely that the electron withdrawing substituent (amide or ester) in *trans* position to the anchoring moiety modifies the electron distribution in the excited state that disfavors electron injection efficiency. Second, based on the results of the PV measurements, two important conclusions can be drawn. First, the “ZnP-TEMPO” dyads outperform the parent reference zinc porphyrins lacking the TEMPO unit. This is the direct consequence of much higher J_{sc} and V_{oc} when the TEMPO moiety is present, resulting in more than twice higher PCEs. The higher photovoltaic performances in DSSCs of the dyads can be logically ascribed to a longer-lived charge separated state resulting from the hole shift from the zinc porphyrin radical cation formed after electron injection in TiO₂. Indeed, the longer distance between the TiO₂ surface and the positive charge on TEMPO most certainly decreases the rate of charge recombination, which enhances the V_{oc} and the J_{sc}.⁷⁵ Although the driving force of the hole shift reaction is weak (about -0.1 eV), it appears sufficient for it to occur quite efficiently.^{22a} Second, the dyad with carboxylic acid anchoring group gives a little more photocurrent density than that with hydroxamic acid. Similar results were reported before and can be ascribed to faster electron injection in TiO₂, probably due to a larger electronic coupling.^{58, 60}

Photocatalytic performances in DSPEC

The photocatalytic performances of the “ZnP-TEMPO” dyads were determined using MeO-Ph-CH₂OH, as it is a classical reference substrate used in many studies with TEMPO catalysts, although that the latter can be most certainly compatible with other alcohols (see below).³⁶ In addition, two different media were explored, first an aqueous electrolyte, since water is the greenest solvent and second acetonitrile, because this organic solvent is potentially relevant for alcohols that are not water soluble. Moreover, acetonitrile is also compatible with CO₂ to envision reduction photocatalysis,⁷⁶ which might be a valuable reaction to perform at the cathode in future tandem photocatalytic devices. The photocatalytic properties were analyzed with the dye chemisorbed on nanocrystalline TiO₂ films, similar as those used in DSSCs, but dipped in a electrolyte containing 50 mM of MeO-Ph-CH₂OH using a standard three-electrode PEC under 1 sun illumination (about 100mW/cm² with 400 nm cutoff filter), with a platinum grid as the counter electrode and a saturated calomel electrode (SCE) as reference. The quantity of MeO-Ph-CH₂OH produced in the electrolyte was determined by gas chromatography after light irradiation.

Measurements in aqueous electrolytes

First, chopped light linear sweep voltammetry (LSV) of **hyd-ZnP-TEMPO** and **hyd-ZnP** between 0.3 V until -0.5 V vs. SCE in borate buffer at pH = 8 with MeO-Ph-CH₂OH was conducted (Figure 4A). The current density is much higher with the dyad than with the zinc porphyrin lacking the TEMPO, evidencing the key role of this organo-catalyst. The photocurrent density decreases as the electrode is bias to negative potentials, however, it remains relatively high until -0.3 V vs. SCE, meaning that, under light irradiation, the photoanode can perform alcohol oxidation at much more negative potential than in the dark (Figure S10). In these latter conditions, MeO-Ph-CH₂OH oxidation arose at an onset potential of 0.74 V vs. SCE, indicating that light irradiation enables a significant gain of *ca.* 1 V. However, compare to the thermodynamic oxidation potential of benzyl alcohol (-0.51 V vs. SCE at pH = 8),⁷⁷ the applied potential is still more positive by about 0.5 V.

Figure 4. (A) chopped light linear sweep voltammetry measurements recorded under white light irradiation (white light Zhaner lamp about 350 W/m²) of **hyd-ZnP-TEMPO** and **hyd-ZnP** on TiO₂ film with 0.1 M borate buffer at pH = 8 containing [MeO-Ph-CH₂OH] = 50 mM, [NaClO₄] = 0.1 M. Scan starts from -0.5 V and ends at 0.3 V vs. SCE with scan rate 5 mV/s; (B) chopped light voltammetry measurements of **hyd-ZnP-TEMPO** recorded at a constant potential of 0 V vs. SCE with (red trace) and without (black trace) MeO-Ph-CH₂OH (10 mM) in the same conditions as above.

Then, chopped light photocurrent densities were recorded at a constant potential of 0 V vs. SCE for **hyd-ZnP-TEMPO** in borate buffer at pH = 8 in presence and in absence of alcohol (Figure 4B). In absence of MeO-Ph-CH₂OH, the photocurrent density is significantly lower than in presence of alcohol, indirectly testifying of the catalysis mediated by TEMPO. Moreover, without alcohol in solution the voltammogram exhibits spikes of larger amplitudes during on and off light cycles. The cathodic spikes, observed when the light is turned off, probably result from charge recombination between the injected electrons in TiO₂ and the oxidized TEMPO, because it cannot be reset to its neutral state by reaction with the alcohol. The spikes directly after light irradiation likely indicate that the photocurrent density is probably limited by mass transport of alcohol to the photocatalyst inside the pores of TiO₂.

Second the impact of the pH was examined, as it is reported that alcohol oxidation with TEMPO is pH dependent and usually works better in basic medium with an optimal pH situated around 10.^{36, 62, 63} Different electrolytes with borate buffer were used between pH 7.5 and 10. The photocurrent responses under long term irradiation of **hyd-ZnP-TEMPO** at different pHs is shown in Figure S19 and the turnover number (TON), turnover frequency (TOF) and faradic efficiency (FE) are gathered in Table 3.

Table 3. Photocurrent densities, TONs, TOFs and FEs measured at different electrolytes with **hyd-ZnP-TEMPO** or **hyd-ZnP + ac-TEMPO** on 1 cm² nanocrystalline TiO₂ films for MeO-Ph-CH₂OH oxidation. Experiments with **hyd-ZnP** : [ac-TEMPO] = 1 mM.

Catalyst	hyd-ZnP-TEMPO					hyd-ZnP + ac-TEMPO
	Borate pH = 7.5	Borate pH = 8	Borate pH = 9	Borate pH = 10	CH ₃ CN + MeImd	CH ₃ CN + MeImd

^acalculated from the quantity of **hyd-ZnP-TEMPO** loaded on the electrode; ^bcalculated from the quantity of **hyd-ZnP** loaded on the electrode and in parentheses from the number of mole of **ac-TEMPO** in solution.

The photocatalytic measurements, recorded under light irradiation at different pHs, provide several interesting information. First, the parent **hyd-ZnP** compound has no photocatalytic activity, since no significant quantity of *para*-methoxybenzaldehyde is found by gas chromatography analysis, even in the optimal conditions with borate buffer at pH = 8. Second in aqueous electrolytes, the dyad **hyd-ZnP-TEMPO** indeed catalyzes the photo-oxidation of MeO-Ph-CH₂OH with a quite high efficiency since the FE is systemically superior or equal to

80% and the DSPEC can reach a sizeable current density of about $200 \mu\text{A}/\text{cm}^2$ at $\text{pH} = 8$. These values are relatively high in comparison with those previously reported for alcohol oxidation in DSPEC with ruthenium catalyst,^{19, 28-30, 33} but also those usually obtained for water oxidation in TiO_2 based DSPECs^{19, 31} or for H_2 evolution in NiO DSPECs,⁷⁸ in which much lower photocurrent densities are typically measured. As anticipated the photocatalytic efficiency is pH dependent, but the maximum rate and efficiency are reached at $\text{pH} = 8$ and decreases at higher pH. Both the rate of photocatalysis, reflected by the current density, and the overall efficiency depend on the intrinsic catalytic activity of TEMPO, the mass transport within TiO_2 pores and the stability of the photocatalyst, both in terms of compound degradation (dye or catalyst) and desorption from the TiO_2 electrode. The observation that the photocurrent decreases more steeply with irradiation time when the pH exceeds 8 suggests higher desorption and degradation rate of the photocatalysts at high pH (Figure S19). However, the absorption spectra of the TiO_2 photoelectrode recorded before and after 1 hour of photolysis at $\text{pH} = 8$ are quite similar; indicating that dye desorption is probably not the main cause of photocatalytic loss in these conditions at $\text{pH} = 8$ (Figure S20). The fact that the photocatalysis decreases for pH above 8, while the electrocatalytic oxidation rate constant of TEMPO increases with pH, could mean that the rate of photocatalysis is limited by the diffusion of the alcohol inside the voids of TiO_2 or that the TEMPO degrades faster in more basic conditions. It was indeed reported that TEMPO is not stable at high pH.⁷⁹ In addition, the assumption that photocatalysis is controlled by mass transport is supported by the chopped light linear voltammetry measurements showing that the steady state photocurrent density is lower than that observed immediately after light irradiation (Figure 4). As generally observed in previously reported DSPEC, the photocurrent steadily decreases upon photocatalysis questioning the cause of this deleterious process (Figure S19). Towards this goal, we have investigated the effect of adding **ac-TEMPO** in the electrolyte to see whether the catalytic activity would be restored. After the run of one hour of photocatalysis in borate buffer, the photoelectrode was transferred in acetonitrile electrolyte and gives a significant photocurrent density (about $200 \mu\text{A}/\text{cm}^2$). Then, after 100 seconds of light irradiation a concentrated solution of **ac-TEMPO** was added into the electrolyte (to reach a final concentration 1 mM in the electrolyte). Interestingly, the photocurrent density did not change, suggesting that the degradation of TEMPO unit in the dyad is probably not the main reason of performances degradation. As a result, we assume that the degradation of the zinc porphyrin during catalysis might be the limiting factor of the long-term stability of the present system. Employing more photo- and/or electro-chemically stable dyes would likely enhance the stability of this type of DSPEC.

Finally, the Incident Photon-to-electron Conversion Efficiency (IPCE) spectrum of the dyad **hyd-ZnP-TEMPO** was recorded in the optimal conditions of borate buffer at $\text{pH} = 8$ (Figure 5). The maximum value reaches ca. 2.6% on the Soret band at 430 nm and the IPCE spectrum matches well with the absorption bands of the zinc porphyrin of the dyad recorded in a thin TiO_2 film. In summary, the dyad **hyd-ZnP-TEMPO** is an efficient photocatalyst on TiO_2 for benzyl alcohol oxidation, since it produces a quite significant photocurrent density and exhibits notable TON and TOF in comparison with other values reported in DSPECs for alcohol oxidation (Table S1).

Figure 5. IPCE spectrum of **hyd-ZnP-TEMPO** recorded at a constant potential of 0 V vs. SCE in borate buffer at pH = 8 and its and absorption spectrum recorded on thin (4 μm) nanocrystalline TiO_2 film without scattering layer.

Measurements in acetonitrile electrolyte

Electro-oxidation of alcohol by TEMPO is abundantly described in organic solvents in the presence of a base, as the formation of aldehyde is accompanied by a proton release. In this study, acetonitrile was used as solvent, because it is compatible with proton reduction and even more interesting for CO_2 reduction as CO_2 is more (7-8 times) soluble in acetonitrile than in water.⁷⁶ Two organic bases, 2,6-lutidine and N-methyl-imidazole (Me-Imd) usually used for this purpose, were investigated here.³⁶ Chopped light photocurrent densities were recorded at a constant potential of 0 V vs. SCE with TiO_2 film coated with **hyd-ZnP-TEMPO** in presence of different concentrations of these two bases (Figure 6). The optimal concentrations of lutidine and N-methyl-imidazole are 10 mM and 100 mM respectively and N-methyl-imidazole gives much higher photocurrent densities than lutidine (about 3 folds). This is certainly due to the higher basicity of N-methyl-imidazole and the possibility to bind axially to ZnP which limits aggregation.

Figure 6. Chopped light voltammetry measurements of **hyd-ZnP-TEMPO** recorded at a constant potential of 0 V vs. SCE in presence of different concentrations of (A) 2,6-lutidine and (B) N-methylimidazole in acetonitrile recorded under white light irradiation (1000 W/m^2) with MeO-Ph-CH₂OH (50 mM) and [LiClO₄] = 0.1 M.

Long term photolysis experiments were then conducted with Me-Imd at 100 mM in acetonitrile to determine the photocatalytic efficiency of **hyd-ZnP-TEMPO** in these conditions (Table 3 and Figure S21). Compared to borate buffer at pH = 8, the efficiency is significantly lower, as the values of TON and TOF are reduced by about a factor of two. This is certainly the consequence of a faster desorption rate of the photocatalyst in acetonitrile, because the dyad is much more soluble in acetonitrile than in the borate buffer (see below).

Measurements with other benzyl alcohol substrates

Although the chosen catalyst **ac-TEMPO** is known to be a very active system for many alcohol substrates,^{36, 62, 80} two other benzyl alcohols: namely benzyl alcohol (Ph-CH₂OH) and *para* trifluoromethyl benzyl alcohol (CF₃-Ph-CH₂OH) an electron deficient substrate were studied both in borate buffer at pH 8 and in acetonitrile electrolyte in presence of methyl imidazole. The average photocurrent densities measured after 500 sec of photocatalysis are gathered in Table 4 and the current *versus* time curves are shown in Figure S22.

Table 4. Photocurrent densities recorded at 500 sec during the photocatalysis experiments with **hyd-ZnP-TEMPO** using three different benzyl alcohol substrates (50 mM).

	MeO-Ph-CH ₂ OH	Ph-CH ₂ OH	CF ₃ -Ph-CH ₂ OH
Borate buffer pH =8	0.20±0.05 mA/cm ²	0.19±0.08 mA/cm ²	0.50±0.05 mA/cm ²
CH ₃ CN+ Me-Imd	0.10±0.02 mA/cm ²	0.10±0.01 mA/cm ²	0.11±0.02 mA/cm ²

It was observed that in borate buffer, benzyl alcohol gives approximately the same photocurrent density as MeO-Ph-CH₂OH, while CF₃-Ph-CH₂OH produces much higher photocurrent density. We interpret this surprising result as the consequence of the higher hydrophobicity of CF₃-Ph-CH₂OH, which probably improves its affinity to the lipophilic environment of the TiO₂ photoanode coated with organic moieties (porphyrin and TEMPO). This is supported by the measurements in acetonitrile, which give higher photocurrent

densities in acetonitrile vs. borate buffer at the beginning of the experiments and similar photocurrent for all three substrates in acetonitrile electrolyte. Overall, these extra measurements show that these ZnP-TEMPO are quite active towards benzyl alcohol substrates in general, in agreement with previous studies,^{36, 62, 80} and that the wettability of the photoelectrode network by the substrate is certainly an important parameter to consider to maximize its contact with the catalytic surface hence the efficiency of the photocatalytic device. This is in agreement with other studies dealing with DSSC using water based electrolytes⁸¹ and DSPEC for water oxidation.⁵⁴

Impact of covalent linkage of TEMPO with ZnP on the photocatalysis

In DSPECs, the catalyst is generally covalently tethered to the photosensitizer or co-grafted with the latter on the surface of the semiconductor.^{31, 32} In some rare cases, it is solubilized in the electrolyte.^{35, 82} The latter approach presents the advantage of being simpler in term of synthesis, but requires a larger quantity of the catalyst and is less practical for its recycling as the latter must be separated from the product in the electrolyte. However, we investigated the photocatalytic performance of **hyd-ZnP** in association with **ac-TEMPO** in the electrolyte. In borate buffer at pH = 8 with 50 mM of MeO-Ph-CH₂OH, increasing concentrations of **ac-TEMPO** from 0 to 10 mM do not change the photocurrent density delivered by the TiO₂ film sensitized by **hyd-ZnP**. This is most certainly attributable to the low solubility of **ac-TEMPO** in water, which prevents reaching a sufficient concentration to quickly react with the oxidized porphyrin before charge recombination. Then, the same experiment was conducted in the acetonitrile electrolyte containing **Me-Imd** by adding increasing quantities of **ac-TEMPO** (from 0 mM to 10 mM, Figure S23). Interestingly, the photocurrent density of the photoelectrode sensitized by **hyd-ZnP** increases upon addition of **ac-TEMPO**, but it reaches a plateau at around 1 mM. Then, long term photolysis experiments were undertaken in these conditions to compare the performances with the system in which the catalyst is appended to the zinc porphyrin (**hyd-ZnP-TEMPO**). Within experimental errors, the performances of the two systems are quite alike (Table 3 and Figure S21). Only TOF is significantly higher with **hyd-ZnP-TEMPO** than **hyd-ZnP** + **ac-TEMPO** and this can be understood as the consequence of a faster hole shift to the catalyst due to the proximity brought by covalent linkage. However, the recovery of the catalytic system is much easier with the dyad (simple rinsing of the photoelectrode) and quantity of the used catalyst is much lower with the dyad (84 nmol *versus* 7000 nmol).

Comparison of hyd-ZnP-TEMPO with HO₂C-ZnP-TEMPO

Having the dyad **HO₂C-ZnP-TEMPO** at our disposition, we have naturally investigated its photocatalytic performance in the optimized conditions both in borate buffer at pH 8 and in acetonitrile with **Me-Imd**. In borate buffer, the photocurrent density was 230 $\mu\text{A}/\text{cm}^2$ after

500 seconds of irradiation, TON, TOF, and FE were 24, 44 h⁻¹ and 89 %, respectively. These values are very close to that measured with the dyad **hyd-ZnP-TEMPO**, indicating that the anchoring group does not significantly affect the photocatalytic efficiency of the system in aqueous medium. This result is in line with the photovoltaic performances recorded in DSSCs which are quite similar with both dyads, let alone a higher J_{sc} with **HO₂C-ZnP-TEMPO**. The low solubility of both dyads in water limits their desorption from the TiO₂ electrode. However, a close inspection of the photocurrent evolution as a function of irradiation time of this dyad with that of **hyd-ZnP-TEMPO** reveals that it decays more abruptly, pointing to a lower stability of carboxylic acid anchor (Figure S24). In acetonitrile electrolyte with **Me-Imd**, the desorption of the dyad **HO₂C-ZnP-TEMPO** is so fast that it prevents to measure the quantity of the produced aldehyde. In conclusion, the replacement of carboxylic acid anchoring group by hydroxamic acid imparts a more robust binding to titania electrode. This enhanced stability has little impact in aqueous electrolyte where the dyad is poorly soluble, but it becomes crucial in acetonitrile electrolyte in which the solubility is sufficiently high, enabling quick desorption of the dyad within few minutes.

Conclusions

A novel photocatalytic system consisting of a zinc porphyrin connected to a TEMPO organocatalyst was prepared and thoroughly investigated for solar driven benzyl alcohol oxidation in a TiO₂ based DSPEC. The dyad **hyd-ZnP-TEMPO** effectively catalyzes methoxybenzyl alcohol oxidation upon light irradiation of a TiO₂ based photoanode coated with this photocatalyst. The optimal performance was observed in aqueous electrolyte at pH = 8, but the system also works with similar efficiency in acetonitrile in presence of N-methylimidazole. However, in acetonitrile electrolyte, the leaching of the photocatalyst from the TiO₂ electrode is undoubtedly the major reason for the decrease of the catalytic performance. On the other hand, in aqueous conditions, the porphyrin degradation is certainly the main cause for the observed reduction of catalytic efficiency. In spite of its low driving force, the hole shift reaction from the zinc porphyrin radical cation occurs quite efficiently, as proved by the enhanced photovoltaic performances in DSSC of the dyad **hyd-ZnP-TEMPO** relative to the parent zinc porphyrin lacking the TEMPO unit. The comparison of the dyad **hyd-ZnP-TEMPO** with the bi-component system “**hyd-ZnP + ac-TEMPO**”, that was possible in acetonitrile, indicates that both approaches give similar performances, but the recovery of the catalyst is easier with the dyad and the quantity of the catalyst involved is much lower. It is observed in this study that hydroxamic acid is undoubtedly a more stable anchoring group than carboxylic acid, but photocatalyst desorption represents a major source of instability only when the system is soluble in the electrolyte. When the dye is very insoluble in the medium, for example here in aqueous borate buffer, the decrease of the catalytic activity can be attributed to dye leaching from the electrode surface. This is another strong argument to develop fully organic photocatalytic systems for DSPECs, since charged transition metal complexes are more prone to water solubility.

The performance of the presented photocatalytic system stands among the highest ever reported for alcohol oxidation in DSPECs (Table S1) and compares very well with most of those reported for oxygen or hydrogen evolution with such photoelectrosynthetic systems. As a result, alcohol photo-oxidation, and particularly those extracted from biomass, represents an attractive reaction to pair with water or CO₂ reduction so as to develop tandem photoelectrosynthetic cells producing valuable compounds at both electrodes. Overall, the present investigation provides several significant information for the development of advanced catalytic photoanodes for DSPECs. First, TEMPO organo-catalyst is not only a cheaper but also a more efficient and more robust catalyst for alcohol oxidation than polypyridine ruthenium complexes classically used for the same purpose in DSPECs. Second, the two electron oxidation of alcohol is an interesting alternative to the four electron oxidation of water to develop higher performing photocatalytic systems for artificial photosynthesis. Indeed, quite good photocurrent densities were measured in DSPEC with a regular tetra-aryl zinc porphyrin, which is, however, a modest TiO₂ sensitizer (as demonstrated with the moderate short circuit photocurrent density recorded in DSSC) and with a weak driving force for hole shift with TEMPO. As a consequence, much higher performances and longer stability could certainly be obtained with the strategy reported here, but by employing a more efficient and more robust TiO₂ sensitizer that also displays a higher oxidation potential than ZnP or a TEMPO derivative with a lower catalytic potential than **ac-TEMPO**. There are indeed many TiO₂ sensitizers^{83, 84} and several TEMPO catalysts⁸⁵ that fulfill these requirements. This attractive strategy might help in designing new catalytic photoanodes for DSPEC that will be more efficient and will provide valuable products in a greener and more sustainable manner.
