Abstract

14 New Caledonia holds one of the largest supergene nickel ore deposits worldwide. Two main ore
15 types are recognized: i) oxide and ii) hydrous Mg silicate types. Our study focuses on the latter type,
16 usually located in elevated parts of the Peridotite Nappe, forming the so-called plateau and slope
17 deposits. Understanding the controls of these ore deposits is important in regard to sustainability of
18 nickel mines; however, to date there are only a few models to refer to, and structural aspects have
19 been generally underestimated.

20 From its formation at a spreading ridge to Eocene obduction, the Peridotite Nappe of New
21 Caledonia underwent several episodes of brittle fracture that mostly preceded weathering. We
22 suggest that inherited fractures coated with serpentine “polymorphs” play a major role in the Ni
23 enrichment process. Fracture analysis shows that this early fracture network share the same
24 orientations with lineaments of peridotite massifs and controlled erosion and plateau dissection
25 during uplift events. The subsequent steep slopes together with circulating waters within
26 serpentinized fractures parallel to underlying valleys lead to slope failure. The collapse of plateau
27 edges provoked plateau decompression and hence multi-directional extension. Gravity-driven
28 faulting caused preferential opening of joints within the hanging walls of faults. The lateral
29 permeability contrast favored preferential weathering and eventually resulted in an increase of Ni
30 content in the saprock. The controlling faults have a specific polyphase infill, which could be a
31 metalotect and a potential guide for nickel exploration.

32

34 New Caledonia holds about 8% of nickel global reserves and ranks fifth among World's nickel ore
35 producers (U.S. Geological Survey, 2017). Nickel ore was formed by tropical weathering of peridotite
36 and is hosted at the base of the weathering profile. Exploration of this type of deposits requires a
37 very dense and expensive drilling pattern due to the high variability of the thickness and grade of the
38 nickel-bearing level.

39 One third of New Caledonia is covered by ultramafic rocks which underwent weathering since the
40 late Eocene. From base to top, the weathering profile is composed of a saprock or saprolite horizon,
41 a limonitic horizon and a ferricrete at the top. Supergene nickel ore deposits correspond to the
42 hydrous Mg-Ni silicate-type ore and oxide-type ore respectively, depending upon the main nickel-
43 bearing mineral phase. These ores are mined within the saprock/saprolite and at the base of the
44 limonite horizon respectively (Brand et al., 1998; Freyssinet, 2005; Butt and Cluzel, 2013).

45 In New Caledonia, ore-forming processes resulting in nickel supergene deposits were not
46 extensively studied until the 2000s due to multiple factors such as abundance of the resource, easy
47 open-cast mining, and complexity of geological controls. However, two main contributions based on
48 the classic *per descensum* model should be mentioned; Trescases (1973), in a geochemical and
49 geomorphological approach, assessed the balance between weathering and erosion during uplift and
50 subsidence, and Legu  r   (1976) was the first to point out the prominent control of the fracture
51 network on Ni mineralization.

52 Understanding the controls of supergene deposits is crucial in regard to sustainability of nickel
53 mines; but, to date there are only a few models to refer to, and mainly targeted to specific deposits.

54 Genna et al. (2005) proposed a model based chiefly on karst-like land forming. Accordingly,
55 sinkholes are associated with landslide-like structures limited at the base by 'listric' faults, in which
56 hydrous Ni silicate ore is concentrated. As a consequence, the discontinuities that controlled nickel
57 concentration were not inherited from basement fractures, but neo-formed as a direct consequence
58 of the weathering process.

59 Cluzel and Vigier (2008) highlighted the synkinematic character of some garnierite crack seals, and
60 suggested that active faulting was associated with newly formed Mg-Ni silicate ore. In addition, they
61 also described polyphase supergene infill of early serpentine-coated faults rooted in the bedrock,
62 thus suggesting some influence of the pre-existing fracture network. The changing nature of infill,
63 from garnierite to silica and finally Fe oxyhydroxides, is considered as a record of the downward
64 migration of the weathering front through time.

65 Cathelineau et al. (2016a) mentioned the strong influence of the inherited fracture network,
66 which is almost systematically reused by supergene infill. Although they report only few evidences of
67 synkinematic character of Ni silicate veins, the presence of hydraulic breccia and preferred
68 orientation of Ni silicate veins indicate some tectonic control. On the basis of paleotemperature
69 estimates of quartz formation, ranging from 50°C to 95°C (Quesnel et al., 2016), Cathelineau et al.
70 (2016a) proposed an alternative 'hydrothermal' model of Ni concentration. Accordingly, meteoric
71 water infiltrated from the surface, was slightly heated at depth and then advected within the
72 peridotites; a process previously proposed by Guillou-Frotter et al. (2015).

73 Fritsch et al. (2016), through a mainly mineralogical approach, described a systematic
74 superimposition of hydrous Mg-Ni silicates on the serpentine-bearing fractures. Authors also argue
75 that meteoric water infiltrating the peridotites would have interacted with a low-temperature
76 hydrothermal field following the cooling of the Peridotite Nappe.

77 More recently, Quesnel et al. (2017) have evidenced lateral transfer of Ni, on the basis of
78 geochemical data from drill-cores of the Koniambo deposit. Accordingly, Ni was transferred
79 downslope from now-eroded topographic highs within the water table of the saprock.

80 Almost all above mentioned models are based upon specialists views (geomorphology,
81 mineralogy, geochemistry, and structural geology), while an integrated approach is still missing.

82 The pragmatic guidelines commonly used by mining geologists are worth taking into
83 consideration. In their experience, nickel mineralization is correlated with the serpentinization
84 degree and density of the fracture network (Orloff, 1968; Pelletier, 1996; Trotet et al., 2014). The role
85 of fractures, either passive (*per descensum* conduits in a static environment) or dynamic (fault
86 motion with hydraulic brecciating and crack seal) has been highlighted by some authors, but on the
87 whole, the importance of the inherited fracture network in the control of Ni deposits has been
88 minored, and, with some exceptions, tectonic aspects have been overlooked.

89 In this paper we propose a refined new model based on structural analysis in several mining areas
90 and DEM analysis that may apply to most silicate-type supergene nickel deposits of New Caledonia.

91 **Geological setting**

92 *Peridotite Nappe*

93 New Caledonia is located in the Southwest Pacific where it forms the emerged northern part of
94 the Norfolk Ridge, a continental ribbon rifted from Eastern Gondwana in the late Cretaceous (Hayes
95 and Ringis, 1973) (Fig. 1A). The Peridotite Nappe (Avias, 1967) is a major litho-tectonic unit obducted
96 in late Eocene time over a substratum composed of several sedimentary and metamorphic units

97 (Paris, 1981; Aitchison et al., 1995; Cluzel et al., 2001). Ultramafic rocks entirely cover the
98 southeastern part of the main island, termed 'Massif du Sud', and crop out in a series of tectonic
99 klippen aligned along the west coast (Fig. 1B).

100 The Peridotite Nappe was emplaced by obduction of the oceanic mantle lithosphere of the
101 Loyalty Basin (Collot, 1987), which corresponds to the eastern part of a larger marginal basin of
102 possible Late Cretaceous age (Aitchison et al., 1995; Cluzel et al., 2001). This basin was inverted and
103 transformed in a fore-arc during the Eocene (Aitchison et al., 1995; Cluzel et al., 2001; Milsom, 2003;
104 Edwards et al., 2015). The northeast-dipping subduction that eventually led to obduction started
105 near the ridge and involved young and hot lithosphere (Ulrich et al., 2010). Subduction inception is
106 time-constrained at ca. 56 Ma by high-temperature amphibolites of the metamorphic sole (Cluzel et
107 al., 2012). Obduction occurred after the latest Eocene, age of the youngest sediments overthrust by
108 the Peridotite Nappe (Cluzel et al., 1998; Maurizot and Cluzel, 2014) and before the Late Oligocene,
109 age of crosscutting granitoids (Paquette and Cluzel, 2007).

110 The Peridotite Nappe is mainly composed of extremely refractory harzburgites and dunites with
111 minor lherzolites (Prinzhofer, 1981; Ulrich, 2010), the latter being mainly located in northern klippen.
112 Peridotites commonly display a compositional layering of alternating harzburgite and dunite (Guillon,
113 1975; Prinzhofer, 1981).

114 The driving mechanism of obduction remains a matter of debate and contrasting models have
115 been proposed: i) blocked subduction (Aitchison et al., 1995; Cluzel et al., 2001); ii) 'push from the
116 rear' mechanism driven by back-arc basin opening (Gautier et al., 2016); or alternatively, iii) "passive
117 obduction", e.g., gravity-driven emplacement triggered by the exhumation of HP-LT rocks
118 (Lagabrielle and Chauvet, 2008; Lagabrielle et al., 2013).

119 Regardless of the mechanism, obduction occurred during a period of warm climate and
120 peridotites were probably weathered soon after emersion. The serpentinite basal 'sole' contains syn-
121 tectonic magnesite veins of supergene origin, which suggest that the Peridotite Nappe probably
122 underwent weathering during the last stages of obduction (Quesnel et al., 2013). Pre- Miocene
123 weathering and erosion of the Peridotite Nappe is recorded by lateritic detritism in Early Miocene
124 sediments (Coudray, 1976), and dated by paleomagnetism of in situ ferricrete (Sevin et al., 2012;
125 Maurizot et al., 2016).

126 *Early fracturation and serpentinization*

127 Fracturation and serpentinization are major features, which are known to control weathering by
128 allowing water circulation, and nickel enrichment through the formation of supergene silicate ore
129 (Golightly, 1981; Pelletier, 1996; Butt and Cluzel, 2013).

130 From spreading to obduction, the peridotites have undergone several episodes of cooling,
131 hydration, and deformation that resulted in the formation of minerals of the serpentine group at the
132 expense of olivine and orthopyroxene (Orloff, 1968; Ulrich et al., 2010). The degree of
133 serpentinization is highly variable and can be pervasive, or alternatively, restricted to veins and
134 fracture walls (Dilek et al., 1997; Andreani et al., 2007; Rouméjon and Cannat, 2014; Rouméjon et al.,
135 2015). Different types of serpentine mineralization are observed: i) diffuse intragranular
136 serpentinization; ii) a network of cm-thick and several m-long joints and faults with serpentinized
137 walls; and, iii) a thick serpentinite mylonite sole at the base of the Peridotite Nappe. Only the first
138 two types, which play a prominent role in supergene nickel enrichment, will be considered here.

139 The diffuse serpentinization consists of a thin mesh developed in olivine cracks usually filled by
140 lizardite. It is commonly randomly oriented and likely formed in static conditions (Evans et al., 2013;
141 Frost et al., 2013; Fritsch et al., 2016).

142 Joints and faults form a dense, complex and polyphase fracture network, which bears various
143 minerals of the serpentine family, namely lizardite, antigorite, chrysotile and polygonal serpentine
144 (Lahondère et al., 2010; Ulrich, 2010; Quesnel, 2015; Cathelineau et al., 2016a). Crystallization of
145 serpentine “polymorphs” depends on many parameters (fluid composition and saturation, surface of
146 reaction, fluid and lithospheric pressure, etc.) and “polymorphs” can form in a large range of
147 pressure and temperature (Andreani, 2003; Evans, 2004; Schwartz et al., 2013; Guillot et al., 2015).
148 Lizardite, chrysotile and polygonal serpentine are known to be stable at temperatures up to 300°C
149 and at low to very low pressure (Evans, 2004; Andreani et al., 2008; Schwartz et al., 2013; Guillot et
150 al., 2015).

151 In the Peridotite Nappe, the serpentine-bearing fracture network usually shows a N130°E
152 dominant trend, locally associated with subordinate N090°E, N045°E and N000°E directions (Leguéré,
153 1976; Moutte and Paris, 1976; Robineau et al., 2007; Jeanpert et al., 2016). These directions are also
154 recognizable as lineaments at island scale (Fig. 1B).

155 *Weathering and Ni-enrichment of peridotites*

156 Weathering of ultramafic rocks is promoted by warm and wet tropical climate, leading to
157 peridotite dissolution and karst-like landforms (Wirthmann, 1965; Trescases, 1973; Latham, 1986;
158 Genna et al., 2005). Weathering of peridotite leaves a considerable residue, which constitutes a thick
159 lateritic regolith (Avias, 1969; Trescases, 1973; Latham, 1986). Infiltration of meteoric water in
160 otherwise impermeable fresh peridotite is enabled by the fracture network (Chételat, 1947;
161 Trescases, 1973; Leguéré, 1976; Genna et al., 2005; Join et al., 2005). Hydrolysis of Fe-Mg silicates
162 (olivine, orthopyroxene and serpentine) allows leaching of Mg and Si while less mobile elements (Fe,

163 Mn, Cr, Ni and Co) remain in residual minerals (chromite) or recombine into newly formed mineral
164 phases (hydrous Mg silicates, Fe oxyhydroxides, Mn- or Co-oxides, etc.). Nickel released by the
165 dissolution of olivine can be incorporated inside the lattice or partly adsorbed at the surface of
166 serpentine (Trescases, 1973; Pelletier, 1996).

167 Typically, the weathering profile in New Caledonia is composed from base to top of four horizons
168 (Eggleton, 2001; Deraisme et al., 2014) (Fig. 2):

- 169 i) Saprolite formed of fractured and partly weathered peridotite, called saprock when there
170 is less than 20% weathering;
- 171 ii) Yellow limonite, in which parent rock texture is still recognizable but considerably
172 flattened;
- 173 iii) Red limonite, in which texture disappears, and where goethite is progressively replaced
174 by hematite;
- 175 iv) Granular (pisolithic) horizon and indurated ferricrete capping the profile.

176 Horizons i) and ii) contains the main Ni mineralizations and depending upon the relative amount
177 of saprolite/saprock and yellow limonite, form two distinct ore types that may coexist in one single
178 deposit. The saprock hosts the hydrous Ni-Mg silicate ore type, whilst yellow limonite hosts the oxide
179 type ore (Troly, 1979; Golightly, 1981; Pelletier, 1996; Freyssinet, 2005; Butt and Cluzel, 2013;
180 Maurizot et al., in press.). In the hydrous Ni-Mg silicate ore, nickel leached from peridotite
181 recombines with Si and Mg to form a mixture of poorly crystallized silicate of the serpentine, talc or
182 sepiolite group, to which should be added chlorite and smectite groups (Fritsch et al., 2016). The Ni-
183 dominated silicate, first discovered in New Caledonia by J. Garnier (1867) is termed garnierite
184 (Liversidge, 1880), whilst the Mg dominated silicate is referred to as deweylite (Bish and Brindley,
185 1978). Both species preferentially precipitate in open spaces, as crack seals and fracture films
186 (Cathelineau et al., 2016b) in the saprock. In the oxide ore, nickel can be incorporated in substitution
187 to iron or adsorbed by goethite minerals in the limonite horizon (Trescases, 1973). Nickel content in
188 the red limonites and ferricrete on top of the weathering profile is not economic at present, they are
189 considered as waste.

190 In New Caledonia, the two ore types coexist in most deposits but silicate ore is dominant in west
191 coast klippen and elevated areas of the northern part of Massif du Sud, while oxide type forms large
192 ore deposits in low lands of the Massif du Sud (Maurizot et al., in press.).

193 The interaction of weathering and fracture network leads to high variability of bedrock
194 morphology and thickness of the weathering profiles, and to overall complexity of orebodies
195 (Trescases, 1973; Genna et al., 2005; Deraisme et al., 2014).

197 Combination of uplift and erosion (Freyssinet, 2005; Chevillotte et al., 2006; Chardon et al., 2008)
198 during a period of climate warming (Lower Oligocene Warm Event and mid-Miocene Climatic
199 Optimum) enhanced by the northward migration of the Australian Plate (Zachos et al., 2001; Zachos
200 et al., 2008; Sevin et al., 2014), resulted in different types of morphology which likely correspond to
201 steps in a continuum (Fig. 1B):

- 202 i) Low-elevated areas with flat surfaces are well developed in the south of Massif du Sud
203 (Trescases, 1973; Chevillotte et al., 2006);
- 204 ii) Plateaus, which are morphologically inverted lowlands, are mainly exposed in the
205 northernmost klippe (Bélep, Tiébaghi, Poum) (Latham, 1986);
- 206 iii) Partly dissected plateaus with stepped planation surfaces and incised glacis, e.g.
207 Koniambo and Boulinda massifs (Latham, 1986);
208 High-elevated, dissected, and mountainous massifs where weathering surfaces are
209 restricted to slopes such as the Mé Maoya Massif.

210

211 **Methodology**

212 *Field methodology*

213 Peridotites are generally covered by a thick regolith, which prevents observation of structures.
214 Therefore, the field study focused on natural cliffs and open-pit mines where saprock and bedrock
215 are best exposed. Fourteen sites have been visited ('grey stars', Fig. 1B) and 520 faults and joints
216 were measured.

217 In the southern part of the island, the 200m-high cap N'Dua cliffs, which correspond to the
218 uplifted NW side of a major fault (Lagabrielle et al., 2005), show good rock exposures allowing
219 fracture analysis on top and at the base of the cliffs (Fig. 3).

220 In mining sites, the field study focused on both plateau and slope deposits (Bailly et al., 2014) in
221 order to compare the structures associated with each type. An exhaustive survey of fractures and
222 their infills/coatings has been undertaken at each site. The results of two representative mine sites
223 are presented:

- 224 i) The Kopéto Massif (Fig. 1B), on which six open-pit mines operating plateau and slope
225 deposits have been studied ('Exploitation', Fig. 4A). In the northeastern part of Kopéto,
226 special attention has been given to the Vieille Carrière site located at 800 m asl;

227 ii) In the north of Boulinda Massif, the Trafalgar site is a slope deposit, which overlooks the
228 river valley oriented N050°E that crosscuts the massif.

229 A focus has been made on the geometry and kinematics of slickensided faults with supergene
230 mineral coatings, thereafter called supergene faults.

231 A distinction has been made between the central fault core or slip surface and the surrounding
232 volume of brittlely deformed wallrock mechanically related to the growth of the fault zone, known as
233 the fault damage zone (Sibson, 1977; Chester and Logan, 1986; Peacock et al., 2000).

234 *Lineament analysis*

235 This field survey was combined with a lineament analysis from a 10 meter digital elevation model
236 (DEM) (DTSI, 2013). In the context of this study, the lineament analysis attempts to distinguish those
237 lineaments which are adapted to underlying structures from those associated with downslope runoff
238 and erosion. The analysis was carried out in the weathered horizon topping the massif and
239 lineaments were drawn where their direction was clearly independent from the direction of the main
240 slope line. Lineaments following the main slope line are organized in a radial pattern, while
241 lineaments adapted to underlying structures extend over erosional features such as crests and rivers.

242 **Results**

243 *Fracture typology*

244 At outcrop scale, fractures may be distinguished on the basis of their coatings or infills. As
245 previously stated, two types of infills/coatings are commonly associated with fractures: primary
246 serpentines and supergene minerals.

247 The four serpentine “polymorphs” have been determined in New Caledonia within fractures of
248 the saprock and bedrock by Raman spectroscopy and others technics (Ulrich, 2010; Quesnel et al.
249 2016). Because the early serpentinization is not the main subject of this paper, serpentine coatings
250 and infills are hereafter simply being termed ‘serpentine’.

251 Three types of supergene silicates may be distinguished: garnierite, deweylite and silica. Silica
252 systematically postdates garnierite and deweylite (Cluzel and Vigier, 2008; Cathelineau et al., 2016a;
253 Fritsch et al., 2016). These supergene infills are found in faults, joints and as matrix or cement in
254 breccia.

255 Observations in extraction zones show that the primary fracture network of the protolith and
256 supergene infills are closely associated. The progressive downward weathering used these pre-
257 existing discontinuities as preferential circulation conduits inducing differential weathering.

258 *Bedrock fracture network*

259 The fresh rock exposures of cap N'Dua cliffs allow a good appraisal of the geometry of the fracture
260 network in the unweathered bedrock. These fractures are coated with serpentine with no supergene
261 coating or infill. The fracture network shows directions N000-020°E, N050-070°E, N090-100°E and
262 N120-140°E with variable dips from 20 to 90° (Fig. 3A). Sets of fractures exhibit variable spacing from
263 a few tens to hundreds of metres, proportional to their length, and cross-cut each other forming
264 dihedral geometry (Fig. 3B). Fracture spacing is constant from base to top and does not increase
265 upward. It is noteworthy that serpentine-coated fractures within the bedrock show the same trends
266 as the ones recognized at island scale.

267 *Distribution of fractures in plateau deposits*

268 Rectilinear segments of most ridges and valleys incising the peridotite massifs are an expression
269 of the main structural directions at the island scale. The Kopéto Massif is crosscut by deep valleys
270 oriented N010°E, N130°E, N050°E and N090°E (Fig. 4A). However, a partly dissected plateau covered
271 by uneven regolith is preserved at an altitude of 1000 m, hosting several orebodies. The plateau is
272 elongated along an E-W direction and lineament analysis from 10 m DEM (DTSI, 2013) shows
273 directions similar to peripheral ridges and valleys (Fig. 4A). Orebodies are elongated, controlled to
274 the north and south by N120°E and N090°E lineaments and subordinate N050°E lineaments (Kermes,
275 Fig. 4A).

276 Most of the fracture network is coated by primary serpentine “polymorphs” indicating their
277 belonging to an inherited fracture field. Fracture analysis shows that these serpentine-coated
278 fractures have the same orientation as the main lineaments (‘Serpentine fracture’, Fig. 4A). But, only
279 fractures conveniently oriented with respect to the plateau edges are reactivated. Reuse of ancient
280 fractures resulted in precipitation of supergene minerals. A prime example is the northern part of the
281 open pit Kermes where serpentine fractures are mainly oriented N020°E and N120°E, while
282 supergene materials are only present in the latter orientation which also limits plateau edges (Fig.
283 4A).

284 Besides, geoelectrical imaging of the regolith, undertaken in the plateau of Tiébaghi (Fig. 1B)
285 (Robineau et al., 2007), confirmed the thickening of the weathering profile in burrows controlled by
286 similar supergene faults.

287 *Distribution of fractures in slope deposits*

288 Slope deposits are arranged in a radial pattern along plateau edges. These are usually controlled
289 by a fracture parallel to the underlying valley while the other sets have subordinate role. On the
290 northeastern side of Kopéto Massif, the pit Vieille Carrière is bounded to the northwest by a crest
291 oriented N060°E. The serpentine fracture network shows various orientations but the pit is
292 controlled by a supergene fault N060°E 35°SE reusing a large serpentine fault plane on the northern
293 side of the pit parallel to the crest and the underlying ravine (Fig. 4A).

294 In this entirely excavated quarry, an exhaustive structural survey has been undertaken (Fig. 4B).
295 Serpentinized fractures and those filled with supergene material as well, display N020°E, N090°E and
296 N130°E average directions. About 70% of the fractures filled with supergene material display
297 serpentinized walls indicating a reopening of inherited fractures (black dashed line, Fig. 4B). The
298 remaining 30% are mainly several cm spaced joints filled with amorphous supergene minerals only;
299 they are generally located in the hanging wall of the main supergene fault.

300 The exploration site Trafalagar (Fig. 5A) shows the morphology of a slope deposit in a pre-
301 exploitation stage. The deposit is bound by a hm-scale fault coated by silica. This fault controls a large
302 slump morphologically recognizable by its detachment scarp and the convex shape of the slipped
303 mass (Fig. 5B). Figure 5C shows an equivalent structure that crops out in a creek oriented E-W. The
304 fault is oriented N050°E 50°NW parallel to the underlying valley and shows a first dextral motion
305 marked by slickensided serpentine, followed by dip-slip motion marked by striated supergene silica.
306 The surface of the weathering profile on top of the slipped mass (Fig. 5B) shows colluvionned
307 elements of ferricrete in-situ, indicating a probable dismantlement of the former profile. It is
308 noteworthy that these detachments are fossils and no recent detachments have been observed.

309 *Supergene fault geometry and associated breccias*

310 Open pit mines within slope deposits and plateau deposits are mainly controlled by faults with a
311 zoned infill at centimeter-scale, which highlights their polyphase character. Indeed, the zoning
312 marked by various supergene minerals reveals that pre-existing fractures filled by older (higher
313 temperature) serpentine minerals have been reactivated in supergene environment. Breccias
314 associated to these faults have been described at cm-scale using six parameters: (1) fragment shape
315 (angular to rounded), (2) size and distribution of fragments, (3) monomictic or polymictic nature, (4)
316 presence of matrix or cement, (5) ratio between matrix (or cement) and fragments and (6) presence
317 of voids and contact between fragments (Taylor and Pollard, 1993; Jébrak, 1997).

318 From the footwall to the hanging wall, the zoning consists of (Fig. 6):

- 319 - the footwall, which exhibits a dense serpentine-filled fracture network with no supergene
320 coating or infill;

- 321 - a thick slickensided serpentine-coating, showing one or several motions;
- 322 - a clast-supported breccia 5 to 50 cm thick, composed of monogenic angular fragments of
323 serpentine and serpentinized peridotite;
- 324 - a fault gouge a few cm thick, composed of breccia consisting of small rounded fragments of
325 serpentine and serpentinized peridotite, imbedded in a matrix of various supergene material:
326 brownish silica (Fig. 5C), deweylite (Fig. 7A) or garnierite (Fig. 7B);
- 327 - a fault 'mirror' commonly showing dip-slip striation. Occasional lenses of deweylite display
328 sigmoidal duplex-like structure, which unambiguously indicate dip-slip motion;
- 329 - a clast-supported monomictic breccia several cm thick, composed of angular fragments in
330 contact with each other and leaving open spaces, a characteristic feature of collapse breccia.
331 The open spaces are partly filled with horizontally layered brownish amorphous silica (Fig. 7C)
332 which possibly indicate a post-kinematic downward infill by silica gel (Kirkpatrick et al., 2013).
- 333 - the highly fractured hanging wall where open joints, 1 to 50 cm wide, have been partly
334 cemented or coated by supergene material (Fig. 5C). Some veins are filled with brownish silica
335 which contains cm-scale angular serpentine fragments extracted from the vein walls (Fig. 7D).
336 These veins, which are absent from the footwall are likely due to hydro-fracturing during
337 faulting.

338 Discussion

339 Structural analysis of already mined areas shows that the preexisting fracture network plays a
340 prominent role in the formation of supergene nickel deposits not only by controlling water
341 infiltration in a passive way but also by increasing fracture opening.

342 Serpentine-filled fractures play a double role as drain and screen. The serpentine infill of fractures
343 seems more resilient to weathering than the peridotite host rock, and generally appear as residue in
344 the limonite horizon (Trescases, 1973; Pelletier, 1996; Bailly et al., 2014; Sevin, 2014; Roqué-Rosell et
345 al., 2016), which means that serpentine infill has a low permeability compared to the rest of the rock.
346 Along steeply dipping fractures, the rock is weathered in a symmetrical fashion indicating that they
347 played the role of a drain. In contrast, along gently dipping fractures, the weathering is more
348 important on the hanging wall indicating that they played the role of a drain and a screen as well,
349 preventing water to flow across the serpentinite coating (Bailly et al., 2014; Sevin, 2014).

350 The serpentine-filled (i.e. pre-weathering) fracture network yields the same orientations as the
351 main lineaments determined by DEM analysis. These orientations closely correspond to valleys and
352 ridges and hence to the bulk massif morphology (Fig. 1B, Fig. 3A and Fig. 4A). This morphology results
353 from erosion of an older smooth surface probably during the early Miocene uplift described by Sevin

354 et al. (2014). The incision of the hydrographic network was guided by pre-existing faults and
355 developed steep unstable slopes on massif edges.

356 On residual plateaus, the weathering profile is usually thicker than on flanks and several authors
357 described the thickness of the weathering profile as an inverse function of slope (Maurizot et al., in
358 press.; Chételat, 1947; Trescases, 1973; Avias, 1978). Furthermore, Quesnel et al. (2017) noted a
359 general Ni- enrichment under thin limonite cover partially eroded or reworked on gentle slopes
360 compared to topographic highs.

361 Slope collapse process is evidenced by the occurrence of normal faults upstream to slope
362 deposits, which reuse serpentine-filled faults parallel to the direction of the underlying valleys (Fig. 3,
363 Fig. 4 and Fig. 5) but also by space opening in the hanging wall of the fault (Fig. 6 and Fig. 7c). The
364 occurrence of similar features on faults that control plateau deposits suggests a similar process.

365 These faults are systematically underlined by supergene matrix-supported breccias and hydraulic
366 breccias in the hanging wall (Fig. 5C, Fig. 5D, Fig. 6 and Fig. 7B) in which the high matrix/element ratio
367 indicated important dilation. Cathelineau et al. (2016a) interpret these breccias as a consequence of
368 low temperature hypogene hydrothermal circulation. However, because these breccias are
369 associated with newly formed supergene minerals (Fig. 7A and Fig. 7B) which are absent of the fresh
370 bedrock, they rather result from supergene processes. In our interpretation, the important dilation
371 exhibited by these breccias is probably due to fluid overpressure. The increase of fluid pressure
372 within the fault resulted in rock failure, followed by sudden pressure drop afterwards, leading to a
373 few centimeter thick gouge.

374 Compared to the hanging wall of the fault, in which fractures have been reopened thus facilitating
375 water circulation (Gudmundsson, 2001), the footwall in which fractures remained tightly closed has
376 been relatively preserved from weathering. We suggest that the dihedral fracture geometry, first
377 described by Sevin (2014), well exposed in cap N'Dua cliffs (Fig. 3B) and in most mining sites, is a
378 major control for horizontal water circulation within the saprock (Jeanpert, 2017) and depending
379 upon the flow direction of the main aquifer, is responsible for lateral variation of Ni grade.

380 As shown by fracture analysis of cap N'Dua cliffs and drill-cores from 200 m depth in the
381 Koniambo Massif (Jeanpert, 2017) (Fig. 1B), the fracture density does not vary significantly upward.

382 Therefore, in order to explain the downward limitation of supergene orebodies, authors invoked
383 the presence of listric faults (referred to as screen faults) (Leguéré, 1976; Genna et al., 2005; Sevin,
384 2014). However, these specific faults are not systematically observed within slope deposits and have
385 never been described within plateau deposits. We argue that the classic *per descensum* model
386 explain the vertical variation of permeability from the saprock horizon to the bedrock. Indeed,
387 although the bedrock is highly fractured, fractures are sealed by serpentine and only reopen in sub-

388 surface allowing the development of the weathering profile. The very low permeability of the
389 bedrock is sufficient to explain the downward limitation of Ni-rich waters.

390 Since the supergene reactivation of preexisting faults only happened in the upper part of
391 peridotite massifs, with no equivalent in the autochthonous basement, and also because there are
392 no modern equivalents of such large-scale slope failure, the elevation gradient cannot account alone
393 for gravity-driven faulting. Therefore, fault reactivation was probably due to reduced frictional
394 strength of preexisting faults provoked by increased water circulation on plateau edges under Late
395 Oligocene and mid-Miocene wet climate (Zachos et al., 2001; Zachos et al., 2008) and intense rainfall
396 periods.

397 In turn, 'supergene' gravity-driven slope collapse increased joint opening in the hanging wall of
398 faults, enhanced rock permeability and hence favored weathering, which eventually resulted in an
399 increase of Ni content in the saprock (Fig. 6 and Fig. 8). Meanwhile, symmetrical normal supergene
400 faults, which display the same features and may be related to similar processes, appeared in the
401 medial part of the massif. Edge collapse resulted in lateral decompression of the plateau and hence
402 multi-directional extension (Fig. 8).

403 **Conclusion**

404 The early serpentinized fracture network plays a relevant role in supergene nickel ore forming
405 processes. Due to the low permeability of peridotite bedrock, this network has been used during
406 weathering by circulating meteoric waters. Field observations and DEM analysis show that this
407 inherited network controlled incision of the pre-Miocene weathering surface and hence the plateau
408 morphology of peridotite massifs. During a second stage of weathering, steep slopes, and water
409 circulation in plateau edges were responsible for slope collapse, which in turn generated
410 multidirectional extension in the massifs themselves. It resulted in increased joint opening and hence
411 permeability, especially in the hanging wall of reactivated faults. Increased permeability enhanced
412 weathering in highly fractured areas, thus forming mineralized burrows within plateaus and due to
413 downward (i.e., centrifugal) circulation of the superficial water table, generated higher-grade slope
414 deposits.

415 The very low permeability of unweathered peridotite of the bedrock cannot allow prominent
416 water circulation and thus, the installation of a deep-seated hydrothermal system. Therefore, nickel-
417 rich waters could not cross the bedrock, which never contains garnierite-like minerals. Instead, Ni-Mg
418 silicate accumulation was restricted to open spaces (rock pores and open cracks) of the saprock; as a
419 consequence, the heat source of low-temperature hydrothermal-like circulation was most probably
420 located within the saprock itself.

421 Mining geologist currently use the serpentinization degree and geomorphology as guides for
422 nickel exploration; in addition to that, we suggest that occurrence of zoned faults described in this
423 paper signal the possible existence of slope and plateau deposits and can be used as an additional
424 metallogenic.

425

Acknowledgments

426 The authors warmly thank Willy Foucher (NMC), Pierre Rossler, Claire Montangerand, Clément
427 Marcaillou, Pierre Epinoux and Aurélie Teau (SLN), Maxime Drouillet (KNS), Cécile Fabre, Denis
428 Fayard (SMGM) and Pascal Pico (Ballande) for giving access to the mining sites, thus enabling this
429 study, and also for sharing their geological knowledge and field experience. The staff of the
430 Geological Survey of New Caledonia is also thanked for welcome, helpful discussions, and support.

431 Moon V. and Proenza J.A. are thanked for throughout and constructive review of an early version
432 of the ms.

433 This study is part of a PhD thesis co-funded by BRGM (French Geological Survey) and the
434 University of New Caledonia. This article is a contribution of the 'CNRT Nickel and its environment' as
435 a part of 'Ophiestruct' project (Geophysics and Structure of New Caledonia Ophiolite).

Figure captions

693 Fig. 1. A) Present-day tectonic configuration of the SW Pacific showing the distribution of major
694 tectonic features. Abbreviations: 3KR, Three Kings Ridge; CFZ, Cook Fracture Zone; LB, Loyalty Basin;
695 LHR, Lord Howe Rise; NC, New Caledonia; NLNZ, Northland New Zealand; NR, Norfolk Ridge; VMFZ,
696 Veining Meisnez Fracture Zone. B) Simplified geological map of New Caledonia showing the location
697 of the studied zones discussed in the text (after Maurizot and Vendé (2009).

698

699 Fig. 2. Typical weathering profile over ultramafic rocks of New Caledonia. Nomenclature after
700 Eggleton (2001) and Deraisme et al. (2014). Nickel content per horizons according to Jebrack and
701 Marcoux (2008).

702

703 Fig. 3. A) Lower hemisphere, equal area projection of the measured serpentinized fault network
704 positioned on a simplified geological map of the Cap n’Dua area. B) Photograph of the Cap n’Dua
705 cliffs and drawing from picture, highlighting the dihedral geometry of the fracture network in
706 unweathered peridotite.

707

708 Fig. 4. A) Geological map of the Kopéto Massif and lineaments interpreted from the Digital Terrain
709 Model (10 m) (DTSI, 2013) and stereonet showing the orientation of the serpentine-filled fractures
710 (straight green lines) compared to those filled with supergene minerals (black dashed lines). B)
711 Stereonets showing the orientations of i) serpentine-filled fractures (on the left), ii) supergene
712 mineralization reusing serpentine-filled fractures (grey straight lines), and iii) neoformed supergene
713 fractures (black dashed lines) in Vieille Carrière open-pit, located in Figure 3A.

714

715 Fig. 5. Normal fault in the Trafalgar exploration site in the northern side of Boulinda massif (Fig. 1B).
716 A) Simplified geological map of the studied area and interpreted lineaments. B) Aerial photograph of
717 the slump mass of the Trafalgar exploration site. C) Zonation of the fault zone associated to
718 detachment scarp. The hanging wall shows open joints filled with supergene silica and is more
719 weathered than the footwall. D) Zoom in the fault core zone. The fault gouge displays a ‘ball-bearing’
720 breccia over a 20 cm thick cataclasite reusing a serpentine fault.

721

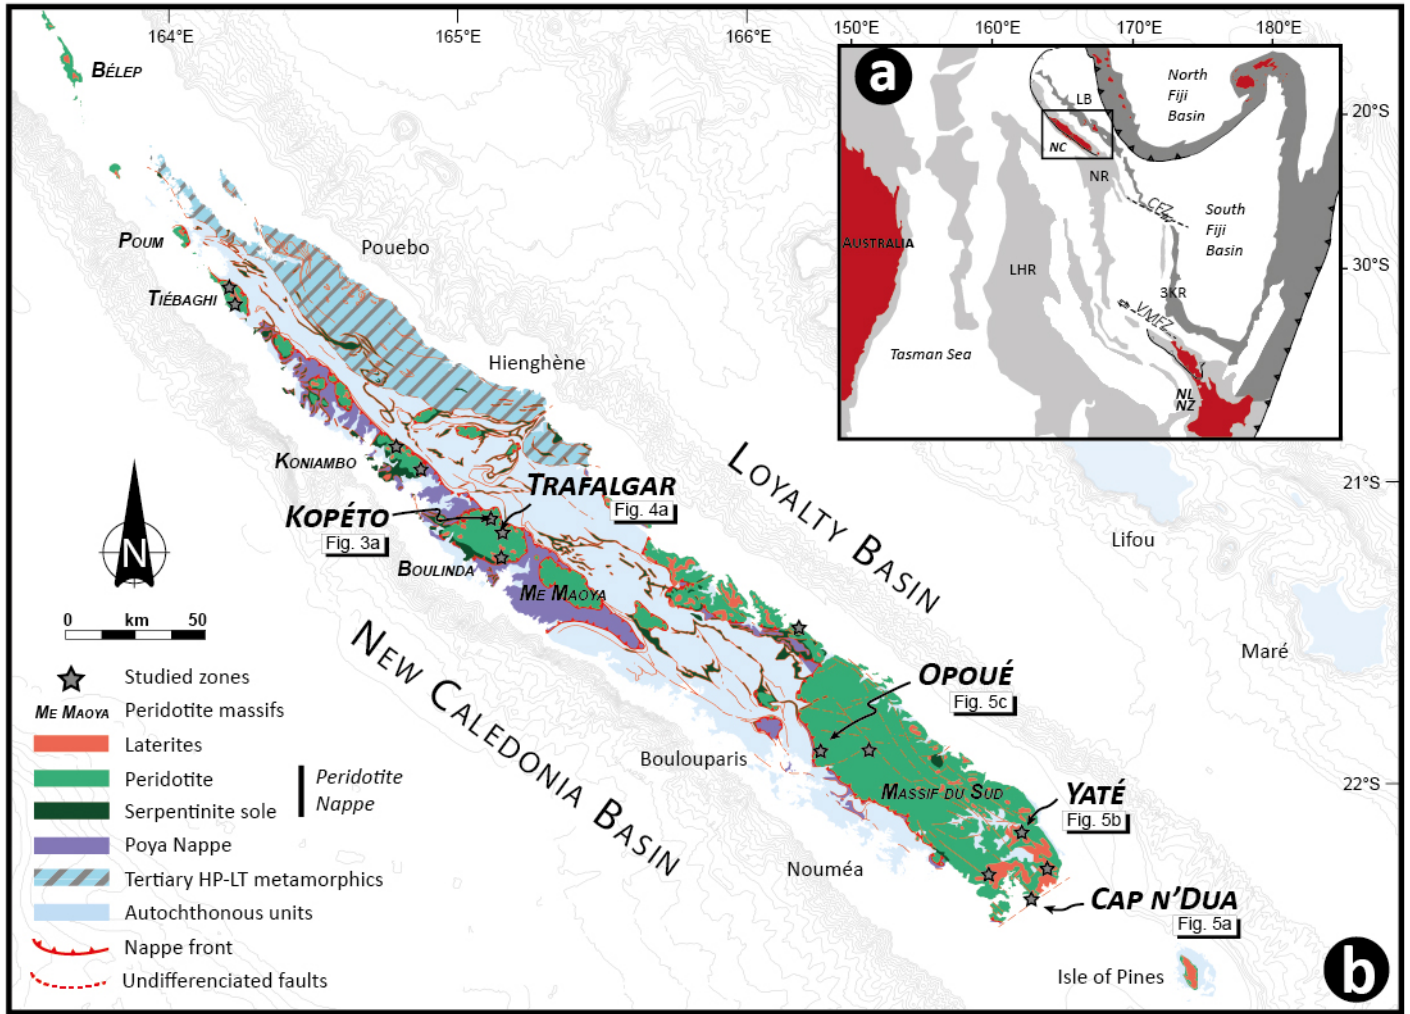

722 Fig. 6. Sketch of supergene fault zoning with zooms on the A) cataclasite of the footwall, B) the fault
723 gouge and C) the collapse breccia of the hanging wall.

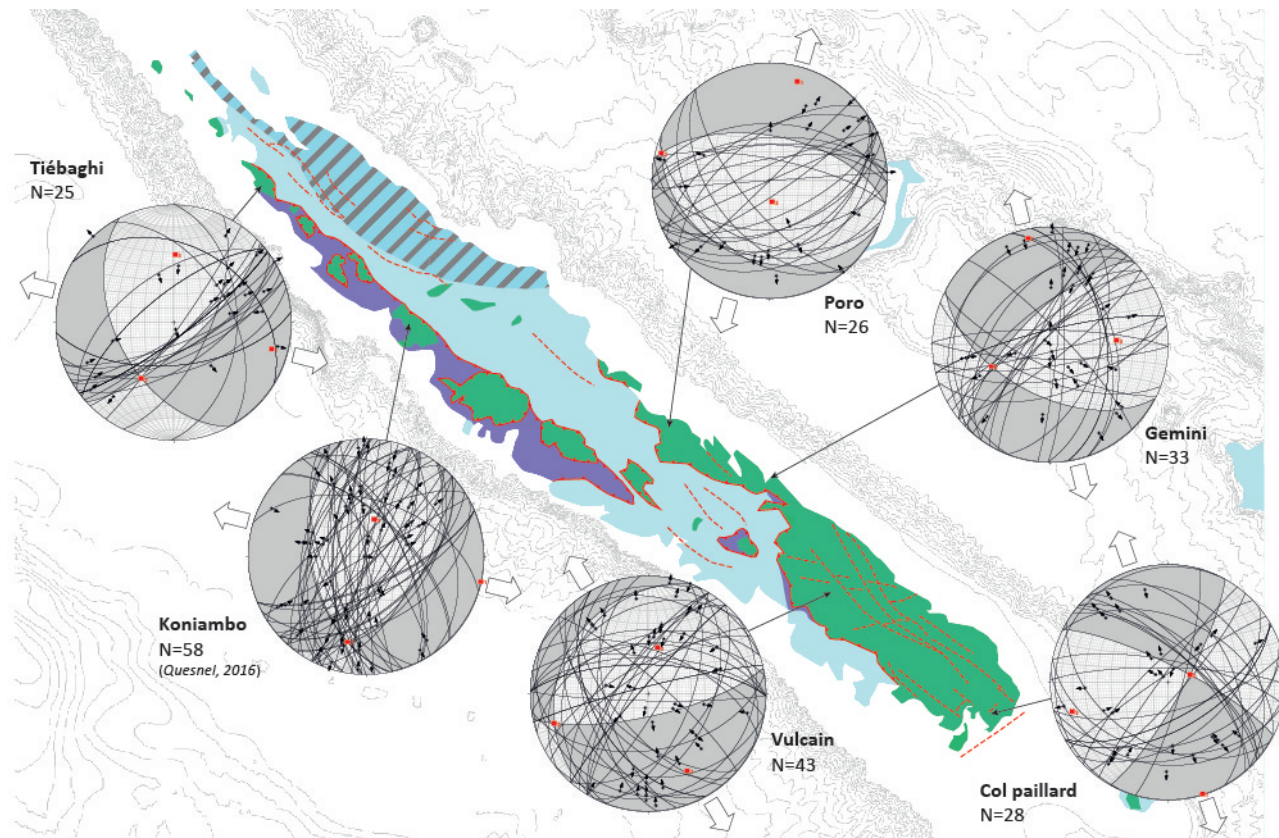

724

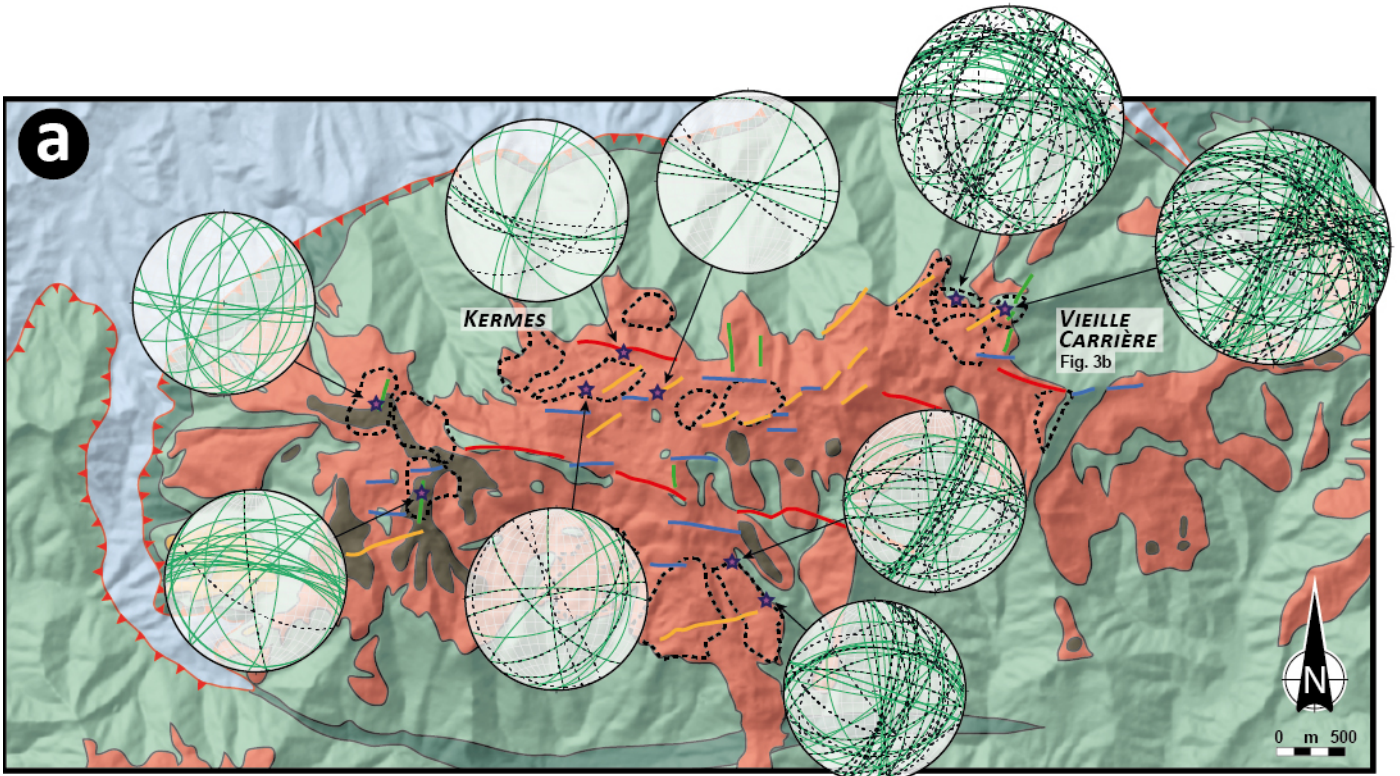

725 Fig. 7. A) Main deweylite-coated fault controlling the pit of Vieille Carrière in the Kopéto massif and
726 B) garnierite fault observed in the Yaté area (localization in Fig. 1B). These faults display the same
727 zonation as Trafalgar fault (Fig. 5). C) Thin section of collapse breccia of the hanging wall of a
728 supergene fault of Opoué mine site (Fig. 1B), the white arrow in upper right corner indicates the line
729 of slope (see description in text). D) Hydraulic breccia within a joint of the hanging wall of the main
730 deweylite fault of 'Vieille Carrière' pit (Fig. 7A).

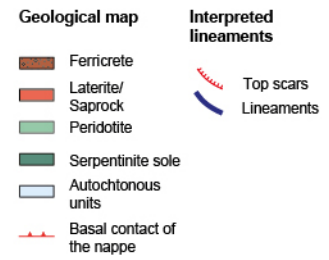

731

732 Fig. 8. Simplified model of gravity-driven faulting in peridotite massifs and its significance for
733 supergene nickel mineralization. Circulating meteoric water reduced the frictional strength, and
734 together with the steep elevation gradient, provoked slope collapse. Meanwhile, normal faults
735 marked by supergene breccia appeared in the inner parts of the massif. In turn, the increasing
736 fracture density in the hanging walls of these faults enhanced permeability and hence favored
737 weathering and eventually nickel concentration.
