ABSTRACT: Intercalation/deintercalation reactions enable introduction/removal of intercalants without destructive structure transformation of host lattices. They are among the most versatile ways to design metastable phases attainable in mild synthesis conditions. Recently, topochemical deintercalation of oxygen anions has opened up an avenue to access new compounds with unusual transition metal oxidation states and interesting properties. So far, the scope of such anion deintercalation was mainly restricted to oxides and their oxyhalide derivatives. But lately we presented a proof of concept study on sulfur deintercalation reaction driven by anionic redox in $\text{La}_2\text{O}_2\text{S}_2$. Here we extend this work and present the design of new members of a family of slightly colored non-centrosymmetric metastable oxysulfides. Our work shows that the reduction with an alkali metal of sulfur dimers in $\text{Ln}_2\text{O}_2\text{S}_2$ ($\text{Ln} = \text{Pr}, \text{Nd}$) precursors leads to the topochemical deinsertion of half sulfur atoms of each S_2 pairs, producing two new metastable $\text{oA-Ln}_2\text{O}_2\text{S}$ ($\text{Ln} = \text{Pr}, \text{Nd}$) phases. The non-centrosymmetric compounds $\text{oA-Ln}_2\text{O}_2\text{S}$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$) evidence second and third harmonic generation effect, suggesting potential applicability of the topochemical route for design of nonlinear optical materials.

INTRODUCTION

Intercalation and deintercalation of a cationic guest (intercalant) are soft chemical processes often at work in lamellar materials without destroying the overall crystal structure of host lattices. That type of reactions draws even more public attention for its use in electrochemical devices after 2019 Nobel Prize.¹ Meanwhile, (de)intercalation processes have been serving as a powerful tool on conception of new solid-state materials. Intercalation / deintercalation reactions usually proceed at much lower temperature than conventional ceramic syntheses and are considered as typical soft chemistry (“Chimie douce”) method. Since in most cases the structural transformations are not destructive these reactions often lead to metastable compounds. For instance low temperature deintercalation of A^+ cations from transition metal dichalcogenides AMoS_2 , led to numerous metastable MS_2 edifices. Metastable CdI_2 -type VS_2 and CrSe_2 were indeed obtained by deintercalation of LiVS_2 and KCrSe_2 in presence of iodine^{2, 3} while cubic TiS_2 was prepared from CuTi_2S_4 using bromine as oxidizing agent.^{4,5}

More recently, the deintercalation of oxygen anions via the use of metal hydrides have also attracted much attention due to the capability of the process to prepare metastable compounds with unusual transition metal oxidation states and interesting properties.^{6, 7} Hence, the low temperature ($T = 200$ °C) oxygen deintercalation in the perovskite nickelate using NaH as reducing reagent,^[7] led recently to the stunning discovery of the superconducting $\text{Nd}_{0.8}\text{Sr}_{0.2}\text{NiO}_2$ compounds with nickel in square planar coordination⁸.

Most of topochemical intercalation reactions, as those aforementioned, rely on redox activity of transition metal cations. This is due both to the well-known, intrinsic ability of transition metals to accept different valence states. In contrast, monoatomic anions with fully occupied valence levels cannot play the role of redox center due to a too high redox potential in their fully reduced form (e.g. O^{2-} , S^{2-}). However, anions also exist in some materials such as chalcogenides and pnictides as molecular dimeric species,^{9, 10} that is, as discrete and covalently-bonded structural entities that have vacant antibonding molecular orbitals available for electron transfer. The redox activity of such polyanionic species was first established in the 80's, when Brec et al. succeeded in the fully deintercalating of lithium in the Li_2FeS_2 ternary sulfide.^{11, 12} This work demonstrated the valence change of the sulfur anions thanks to the formation of sulfur dimers (S_2)²⁻ within the delithiated compound. Since then, the redox activity of anionic dimers or oligomers was observed in many polychalcogenides,¹⁰ and was found more recently to play an important role in Li-rich oxides.^{13, 14} The intense researches on the redox activity of anions in both oxides^{13, 15} and chalcogenides^{16, 17} has established itself as a very active new domain called “anionic redox”. In that framework some work is now focusing on the topochemical intercalation of metal species based on anionic redox only. In particular, it was shown that chalcogen dimers (Q_2)²⁻ ($\text{Q} = \text{S}, \text{Se}$) embedded in lamellar compounds are effective anionic redox centers towards reductant metal species (M^0).¹⁸ For example, the low temperature reaction of metallic copper (Cu^0) with $\text{La}_2\text{O}_2\text{S}_2$, a layered materials with $2/\infty[\text{La}_2\text{O}_2]$ slab well separated by (S_2)²⁻ dimers, leads to the topochemical insertion of copper to form

$\text{La}_2\text{O}_2\text{Cu}_2\text{S}_2$. This process is driven by electron donation from elemental copper to the empty molecular orbital of $(\text{S}_2)^{2-}$ dimers, which triggers both the cleavage of S-S bonds and the migration of metal to construct infinite copper sulfide layers (Figure 1).

Figure 1. Illustration of the two different anionic redox topochemical routes enabled by the reaction of chalcogenide dimer with different metal species. Breaking of the chalcogen-chalcogen bonds is followed either by intercalation of the metal species or by deintercalation of the part of its anions.

On the other hand, the reactivity of these $(\text{S}_2)^{2-}$ dimers can also lead to deintercalation of sulfur anions instead of intercalation of the metal species (Figure 1).¹⁹ In this work, we follow our preliminary investigation of the deintercalation of sulfur in $\text{La}_2\text{O}_2\text{S}_2$,¹⁹ to show that the whole series of isostructural homologues $\text{Ln}_2\text{O}_2\text{S}_2$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$) equally undergo deintercalation of sulfur anions when treated with alkali metals (Na, K, Rb) at mild temperature. This topochemical reaction is reversible and conserves the structural features of the Ln_2O_2 layers (*vide infra*). At the end, the anionic redox reaction produces a family of metastable compounds hereafter labeled $\text{oA-Ln}_2\text{O}_2\text{S}$ (notation by Pearson symbol) that are non-centrosymmetric compounds and potentially interesting as nonlinear optical materials.

Experimental section

Preparation of the $\text{La}_2\text{O}_2\text{S}_2$ precursors.

The synthesis of pure $\text{Ln}_2\text{O}_2\text{S}_2$ precursors ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$) was performed in vacuum sealed tubes containing a mixture of Ln_2O_3 , Ln and S (Ln_2O_3 from Aldrich 99.9%, Ln from Alpha Aesar 99.9% and S from Aldrich 99.99%) in stoichiometric ratio and annealed at 650°C during 120 hours.

Topochemical conversion from $\text{Ln}_2\text{O}_2\text{S}_2$ to $\text{oA-Ln}_2\text{O}_2\text{S}$.

The topochemical synthesis of $\text{oA-Ln}_2\text{O}_2\text{S}$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$) metastable compounds was carried out by mixing the $\text{Ln}_2\text{O}_2\text{S}_2$ precursors with one alkali metal (Li (Aldrich, 99%), Na (Aldrich, 99%), K (Aldrich, 98%) or Rb (Aldrich, 98%)) in a 1:2

molar ratio. The mixtures prepared under argon atmosphere were then loaded into silica tubes that were evacuated ($\sim 10^{-3}$ torr) and sealed. The sealed tubes were then heated at temperature ranging from 200 °C to 350°C and held at that temperature for 2 h to 10 h (e.g. 340°C during 10h for most samples). Finally, the sealed tubes were gradually cooled to room temperature and subsequently opened under argon atmosphere. The resulting powders were successively washed with isopropanol, ethanol and distilled water to dissolve the alkali salts formed during the reaction and then dried in an oven at 60°C. When using Na, K or Rb this method yielded pure $\text{oA-Ln}_2\text{O}_2\text{S}$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$) compounds. The same method was tested for a mixture of Lithium and $\text{La}_2\text{O}_2\text{S}_2$ but an incomplete reaction was observed. It led to partial sulfur deintercalation of the oxysulfide precursor and to a passivation layer on the remaining Li metal pieces. The $\text{oA-Ln}_2\text{O}_2\text{S}$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$) powders are transparent but their color depends on the rare earth used *i.e.* colorless for $\text{Ln} = \text{La}$, slightly greenish $\text{Ln} = \text{Pr}$ or slightly bluish for $\text{Ln} = \text{Nd}$. All products are stable under ambient atmosphere. In the case of $\text{Ln}_2\text{O}_2\text{S}_2$ the same reaction performed at 200°C or 350 °C gave identical results, *i.e.* pure $\text{oA-La}_2\text{O}_2\text{S}$ without any trace of $\text{hP-La}_2\text{O}_2\text{S}$.

Intercalation of sulfur anions into $\text{oA-Ln}_2\text{O}_2\text{S}$ ($\text{Ln} = \text{La}, \text{Pr}$).

The $\text{oA-Ln}_2\text{O}_2\text{S}$ (ca. 200 mg) powders ($\text{Ln} = \text{La}, \text{Pr}$) were combined with S flakes (Aldrich, 99.99+%) in a 1 : 0.5 or 1 : 1 molar ratio and ground in an agate mortar under argon atmosphere. Then the mixture was pressed into pellets and sealed in an evacuated ($\sim 10^{-3}$ torr) silica tube. The tubes were heated to 200 °C at a rate of 100 °C/h⁻¹ and held at this temperature between 2 h and 4 h before gradual cooled down to room temperature. This method yielded pure powders of $\text{Ln}_2\text{O}_2\text{S}_2$ ($\text{Ln} = \text{La}, \text{Pr}$) when a $\text{oA-Ln}_2\text{O}_2\text{S} : \text{S}$ ratio 1 : 1 was used for complete intercalation (see figure S5). Conversely when a half intercalation was targeted using a $\text{oA-Ln}_2\text{O}_2\text{S} : \text{S}$ ratio 1 : 0.5 a new phase with formulation $\text{oA-Ln}_4\text{O}_4\text{S}_3$ was obtained often with traces of the $\text{oA-Ln}_2\text{O}_2\text{S}$ precursor (see figure S6). In the case of $\text{oA-Ln}_2\text{O}_2\text{S}$ a sulfur intercalation was also successfully attempted at lower temperature $T = 150$ °C but it required longer annealing time (48 h).

Preparation of stable $\text{hP-La}_2\text{O}_2\text{S}$ compounds.

Stable $\text{hP-Ln}_2\text{O}_2\text{S}$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$) were obtained by decomposition of the $\text{Ln}_2\text{O}_2\text{S}_2$ precursors at 900°C. $\text{Ln}_2\text{O}_2\text{S}_2$ precursors were pressed into pellets and loaded into silica tubes that were sealed under vacuum ($\sim 10^{-3}$ torr). The tubes were heated at 900°C using a ramp of 100°C/hours and then held at this temperature for 2 hours. After cooling to room temperature a sulfur deposition was observed at one tube end. The powders obtained at the other tube extremities were pure $\text{hP-Ln}_2\text{O}_2\text{S}$ compounds as confirmed by XRD analysis (see Figure S7).

Alternatively, the stable $\text{hP-Ln}_2\text{O}_2\text{S}$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Nd}$) polymorphs were also obtained by transformation of $\text{oA-Ln}_2\text{O}_2\text{S}$ metastable phases. For these experiments a pressed pellet of $\text{oA-Ln}_2\text{O}_2\text{S}$ were loaded into vacuum-sealed silica tubes ($\sim 10^{-3}$ torr), and held for 2 hours at 400°C. After cooling at room temperature, a pure powder of $\text{hP-Ln}_2\text{O}_2\text{S}$ compound was obtained as characterized by XRD (see Figure S8).

Chemical analysis

Semiquantitative chemical analyses of all oA-Ln₂O₂S (Ln=La, Pr, Nd) samples, were performed using a scanning electron microscope JEOL 5800 equipped with an energy dispersive X-ray (EDX) microanalyzer. The chemical analysis of oA-Ln₂O₂S revealed the presence of the three elements Ln, O and S but due to the low atomic number of oxygen a quantitative result was not obtained for this element. The relative atomic percentage ratios (Ln/S) measured for the different La, Pr, Nd derivatives are respectively La/S= 64.4 (2)/35.6(1), Pr/S= 65.2(2)/34.8(1) and Nd/S= 66.5(4)/33.5(2). Assuming two lanthanum and oxygen in the atomic composition the EDX analysis gave the following compositions La₂O₂S_{1.09(1)}, Pr₂O₂S_{1.06(1)}, Nd₂O₂S_{1.01(2)} in good agreement with the expected one oA-Ln₂O₂S.

Raman spectroscopy

Raman spectra of all samples were recorded in backscattered geometry using a Renishaw inVia spectrometer equipped with a 514 nm argon laser. The laser power was maintained at 0.15 mW. At least two different locations of the different powder samples were analysed to ensure their homogeneity.

Magnetic measurements

Magnetic measurements were performed using a Quantum Design MPMS SQUID magnetometer in the 300K-1.5K temperature range. Zero field-cooled (ZFC) and field-cooled (FC) susceptibility were measured on a powder sample of oA-Pr₂O₂S (m = 55.6 mg) under an applied field of 1000 Gauss. Data were corrected from the sample holder contribution. The core diamagnetism was calculated using tabulated Pascal increments. and a contribution \square_{dia} of $-9.4 \times 10^{-5} \text{ cm}^3/\text{mole}$ was subtracted from the measured data.

Diffuse-reflectance spectroscopy

The diffuse-reflectance spectra of all samples were recorded on a Varian Cary 5G spectrometer equipped with a 60 mm diameter integrating sphere and computer controlled using the Cary WinUV software. Diffuse reflectivity was collected from 250 nm to 1000 nm (i.e. 1.24 eV – 4.96 eV). The sample reflectance R was calibrated using Halon powder (Varian) as the reference of 100% reflectivity and plotted as the Kubelka-Munk function $K / S = (1 - R)^2 / (2R)$. Estimation of optical band gap E_g was directly made from Kubelka-Munk function K / S without converting them into Tauc plots.

SHG measurements

The SHG measurements were performed at room temperature using an optical parametric amplifier (Spectra Physics TOPAS Prime) excited by a titanium sapphire regenerative (Ti-Sap) amplifier (Spectra Physics Solstice) as the excitation light source, with 100 fs pulse width, 1 kHz repetition rate, 1.0 mJ=(pulse·cm²) excitation density, and wavelengths of 1200 nm. Sample luminescence was monitored using a spectrometer (Jovan-Ybon Triax550) equipped with a charge-coupled device (Andor Technology DU420A).

RESULTS AND DISCUSSION

Ln₂O₂S₂ (Ln=La, Pr, Nd) is a series of compounds to test anionic redox reactivity. These compounds are all isostructural with La₂O₂S₂ ($\text{La}^{3+}_2\text{O}^{2-}_2(\text{S}_2)^{2-}$) and possess a layered structure with sulfur-sulfur dimers sandwiched by Ln₂O₂ fluorite type layers.²⁰ The electronic band structure of these compounds reveal that the empty $\sigma_{\text{S-S}}^*$ and filled $\pi_{\text{S-S}}^*$ bands are laying on both sides of the Fermi level.²¹ It means that the only redox active species in this material is the anionic sulfur dimer (S₂)²⁻ that has its highest σ^* level available to host electrons of a reductant.

Figure 2. X-Ray diffraction patterns obtained after reaction of La₂O₂S₂ with alkali metals A= Na, K (before washing), Rb (after washing) at 340°C during 10h. The lower panel shows for comparison the X-Ray pattern of the precursor La₂O₂S₂ while the upper panel shows the pattern of the known compound hP-La₂O₂S.

In this study we have first tested the reactivity of the La₂O₂S₂ precursor toward the electropositive alkali metals i.e. A = Na, K, Rb. Our preliminary results conducted at low temperature (200 °C) with rubidium demonstrated the sulfur deintercalation from the precursor.¹⁹ The same can be observed when Na or K alkali metals were used as reducing agents. Their synthesis conditions are detailed in the experimental part in SI.

Figure 3: (a) Representation of the structure of the oA- $\text{La}_2\text{O}_2\text{S}$ phase. The structure is projected along the b and c directions and the coordination polyhedra of the La and S atoms are shown. (b) Comparison with the structure of the stable phase hP- $\text{La}_2\text{O}_2\text{S}$.

Figure 2 compares the X-ray diffraction patterns of the products obtained when reacting with Na, K and Rb. These syntheses yielded the same product with appearance of A_2S alkaline salts that drive the reaction (see the Na and K reactions). These salts could be washed away with isopropanol (see the reaction with Rb for instance).

The results obtained with ($\text{A} = \text{Na}, \text{K}, \text{Rb}$) points towards the formation of $\text{La}_2\text{O}_2\text{S}$, which was fully confirmed by energy disperse X-ray spectroscopy (EDX) experiments (see supplementary information). The formation of these products is remarkable as their X-ray diffraction patterns are not comparable with the one of thermodynamically stable polymorph hP- $\text{La}_2\text{O}_2\text{S}$ (see comparison in Figure 2) whose structure depicted in Figure 2 crystallizes in the hexagonal space group P-3m1. The reactivity of $\text{Pr}_2\text{O}_2\text{S}_2$ and $\text{Nd}_2\text{O}_2\text{S}_2$ towards alkali metals was equally examined (See SI for the detailed synthetic protocols). In both cases, the results are similar to the one observed with the $\text{La}_2\text{O}_2\text{S}_2$ precursor. The X-Ray diffraction patterns of all $\text{Ln}_2\text{O}_2\text{S}$ compounds look quite similar (See Figure S1) with that of the lanthanum counterpart while the EDX confirm the formation of

$\text{Pr}_2\text{O}_2\text{S}$ and $\text{Nd}_2\text{O}_2\text{S}$ (see analysis results in SI). In fact, these patterns correspond to the one of the new polymorph of $\text{La}_2\text{O}_2\text{S}$ that was successfully predicted using the genetic algorithm USPEX (see reference 19 for details). This calculation revealed a metastable phase lying just above in energy of the stable phase hP- $\text{La}_2\text{O}_2\text{S}$. Figure 3 shows the structure of this predicted metastable phase called hereafter oA- $\text{La}_2\text{O}_2\text{S}$ as it possess an orthorhombic space group Amm2. The predicted structure of oA- $\text{La}_2\text{O}_2\text{S}$ was used as first model to refine the X-ray powder diffraction patterns of all $\text{Ln}_2\text{O}_2\text{S}$ ($\text{Ln}=\text{La}, \text{Pr}, \text{Nd}$) compounds. These refinements converged rapidly and gave satisfying results as shown in Table 1 and Figure 4. The results of the refinements are summarized in Table 2 and Table 3. More details are given in supplementary information (Table S1, S2 and S3).

The reactivity of the pairs was also monitored using Raman spectroscopy. Figure S2 compares the Raman signature of all precursors $\text{Ln}_2\text{O}_2\text{S}_2$ ($\text{Ln}=\text{La}, \text{Pr}, \text{Nd}$) with the one of the metastable $\text{Ln}_2\text{O}_2\text{S}$ phases. In the precursors, the stretching modes of the S-S bonds appears as the most prominent doublet peak

around 500 cm^{-1} . This doublet completely disappears in all metastable $\text{Ln}_2\text{O}_2\text{S}$ ($\text{Ln}=\text{La, Pr, Nd}$) phases. The Raman study confirms therefore that the reaction of alkali metals with the $\text{Ln}_2\text{O}_2\text{S}_2$ precursors ends up in the breaking of all the S-S dimers. It suggests that the reaction involves only the valence change of the anions from $(\text{S}_2)^{2-}$ to S^{2-} . This hypothesis is supported by magnetic susceptibility measurements specifically carried out on the $\text{Pr}_2\text{O}_2\text{S}$ compound. Figure S3 shows that the magnetic susceptibility of this compounds follows a Curie-Weiss law, $\chi = C/(T - \theta)$ in the whole temperature range (4-

300K). The Weiss temperature $\theta=24.79\text{ K}$ is positive indicating the presence of ferromagnetic interaction. The experimental effective magnetic moments $\mu_{\text{eff}}=3.47\text{ }\mu\text{B}$ deduced from the curie constant $C=1.5\text{ cm}^3\text{ K mol}^{-1}\text{ C}$ is in good agreement with the effective magnetic moments calculated for Pr^{3+} ions ($\mu_{\text{eff}}^{\text{calc}}=3.58\text{ }\mu\text{B}$). It excludes therefore a valence change of the praseodymium cation during the sulfur deintercalation reaction.

Figure 4. Rietveld refinement of the X-ray powder pattern of the oA-Ln₂O₂S (Ln=La, Pr, Nd) phases. (a) La compound, (b) Pr compound and (c) Nd compound. For each compound the insert shows a picture of a pressed pellet of the powder.

All these measurements suggest therefore a reaction based on a pure anionic redox mechanism that may be written:

with Ln=La, Pr, Nd and A= Na, K, Rb.

This reaction leads to the deintercalation of half of the sulfur atoms from Ln₂O₂S and produce a new polytype of Ln₂O₂S, i.e. oA-Ln₂O₂S (see Figure 2). All oA-Ln₂O₂S (Ln=La, Pr, Nd) compounds crystallize in the non-centrosymmetric space group Amm2 and are isostructural. As expected for steric reasons, Table 1 reveals that the cell parameters and cell volumes decrease going from the La to the Pr and Nd variants. The structural arrangement of the new oA-Ln₂O₂S compounds (Figure 3) is built upon the stacking of [Ln₂O₂] slabs alternating with isolated sulfur atoms. Both hP- and oA-Ln₂O₂S polymorphs are common in such alternate stacking while structures within the respective [Ln₂O₂] slabs differ drastically. Namely, the oA-Ln₂O₂S compound exhibits [Ln₂O₂] fluorite-type (001) slabs, while the hP derivatives exhibits [Ln₂O₂] fluorite-type (111) slabs. Consequently, the sulfur atoms present different lanthanide polyhedra in the two polymorphs, i.e. trigonal prism in the oA phase and octahedron in the hP phase (see Figure 3). The Ln atoms show

also different environments. In the hP structure type, Ln atoms occupy a single coordination site composed of four oxygen atoms and three sulfur atoms. In contrast, there are two different Ln sites in the oA-structure type composed of four oxygen atoms and two or three sulfur atoms (see Figure 3). Clearly the oA-La₂O₂S phase is directly inherited from the La₂O₂S precursor built up from an alternate stacking of (001) fluorite-type [La₂O₂]²⁺ infinite layers separated from each other by discrete (S₂)²⁻ sulfur dimers aligned in parallel to the layers.²⁰ The sulfur deintercalation does not modify therefore the [La₂O₂] slab but only involves a shift of half [La₂O₂] layers along the $\frac{1}{2}(b+c)$ direction of the precursor as shown in Figure S4.

Figure 5 : Diffuse-reflectance spectra measured on (a) oA-Ln₂O₂S (b) hP-Ln₂O₂S and (c) Ln₂O₂S₂ (Ln = La, Pr, Nd). The band gap energies (E_g) of all compounds are indicated in each panel and their pre-peak energies are put in parentheses when necessary.

This observation supports the topochemical nature of the sulfur deintercalation reaction. To learn more about this process, we investigated the low temperature reversibility of the reaction i.e. the sulfur intercalation into oA-Ln₂O₂S.

To this end, the powders oA-Ln₂O₂S easiest to synthesize (i.e. with Ln= La, Pr) were mixed with elemental sulfur in the 1:1 atomic ratio and heated at 200 °C. The XRD analysis of the products (Figure S5) confirmed the back conversion to the original Ln₂O₂S materials with no detected impurities. These experiments confirm the complete reversibility of the temperature-assisted sulfur intercalation/deintercalation reaction based

on a pure anionic redox process. Moreover partial intercalation or deintercalation experiments undertaken with oA-La₂O₂S have shown that the reaction involves the formation of at least one intermediate phase with composition La₂O₂S_{1.5} (i.e. La₄O₄S₃, Ln³⁺O²⁻₄(S₂)²⁻S²⁻) (see Figure S6). The structure of this intermediate phase La₄O₄S₃ is also inherited from the Ln₂O₂S₂ precursor (see ref 19 for structure determination). The same behavior is also observed in the case of partial intercalation experiments undertaken with oA-Pr₂O₂S. The diffraction pattern evidences new peaks in good agreement with the simulated pattern of a Pr₄O₃ phase (SG=Amm2; a=8.3546(13), b=3.9773(5), c= 12.5481(13)) isostructural with La₄O₄S₃ (see Figure S6).

Figure 4 displays in inserts the pictures of pressed pellets of oA-Ln₂O₂S powders. The La derivative is colorless while the Pr and Nd derivatives show, respectively a slight green and blue hue coming from the 4f transitions on the lanthanide ions. The Kubelka-Munk transformed diffuse-reflectance spectra of oA- and hP-Ln₂O₂S powders, as well as their Ln₂O₂S₂ precursors are displayed in Figure 5. The synthesis conditions for preparation of the stable hP-Ln₂O₂S compounds is described in supplementary information and their powder X-ray diffraction patterns are displayed in Figures S7 and S8. All Ln₂O₂S samples except hP-Pr₂O₂S exhibit an absorption preceded by a pre-peak. Overall absorption shift towards high energies along the Pr < Nd ~ La sequences for the oA-series with pre-peaks and absorption thresholds at 2.96 and 3.31 eV, 2.98 and 3.84 eV and 3.07 and 3.88 eV for oA-Pr₂O₂S, Nd₂O₂S and La₂O₂S, respectively. In contrast, the absorptions associated to hP-Nd₂O₂S (2.83 and 3.80 eV) are significantly lower in energy than the ones hP-La₂O₂S (3.48 and 4.13 eV) while hP-Pr₂O₂S exhibit only a steep onset at 3.47 eV. Sharp and low-intense absorptions are observed in the visible range for Nd and Pr containing Ln₂O₂S phases in relation with Laporte forbidden f-f transitions. Their weakness account for the pale observed green and blue colors for Pr₂O₂S and Nd₂O₂S. These bands are located at the same energy for the oA- and hP- polymorphs and the Ln₂O₂S₂ precursors for Pr and Nd lanthanides. La₂O₂S₂, Pr₂O₂S₂ and Nd₂O₂S₂, display a yellow color associated to $\pi_{S-S^*} \rightarrow \sigma_{S-S^*}$ transitions.

Given their (almost) colorless and non-centrosymmetric character, the oA-Ln₂O₂S powders were subsequently tested for the possible generation of light with a doubled frequency (second harmonic generation, SHG). Figure 6 shows the non-linear optical responses of oA-Ln₂O₂S samples in the 350-700 nm range for excitation at 1200 nm at room temperature. These measurements evidence that all oA-Ln₂O₂S compounds exhibit a SHG activity at 600 nm, which is consistent with their non-centrosymmetric structure. At the same time, a relatively large third harmonic generation (THG) peak is also observed at 400 nm for all compounds. THG is expected regardless the crystal symmetry but it is often studied in non-centrosymmetric ferroelectric crystals in order to take an advantage of their strong nonlinear light-matter interactions.²² Accordingly, their THG signals became much weaker than SHG. On the contrary, many typical centrosymmetric crystals such as α -BBO, calcite, and rutile equally exhibit THG despite of their SHG inertness.²³ In particular, some centrosymmetric crystals like Cu₂O are known to exhibit strong THG signal with very weak signal at double frequency.²⁴

Figure 6 : Spectra of SHG and THG of oA-Ln₂O₂S compounds ((a) Ln=La; (b) Ln=Pr; and (c) Ln=Nd) under excitation at 1200 nm.

The spectra in Figure 6 resemble rather those centrosymmetric crystals despite the non-centrosymmetric crystal structure of oA-Ln₂O₂S. This contradictory feature implies that oA-Ln₂O₂S may exhibit exceptionally strong third-order optical susceptibility $\chi^{(3)}$, and/or a weak polar structure resulting in small $\chi^{(2)}$ coefficient. To gain insights into the weak SHG response, the dipole moments for LaO₄S₂ and LaO₄S₄ polyhedra were therefore calculated using a simple bond-valence approach.²⁵ The dipole moments of these polyhedra are estimated to be 1.71 and 2.16 D (Debye: 10^{-18} esu cm) in magnitude, respectively. This is smaller than typical dipole moments found in other mixed anion polar building blocks, e.g., 9.75-11.76 D for GeOS₃,²⁶ and 3.03-5.70 for ZnOS₃.²⁷ Furthermore, the dipole moments of the

La-centered polyhedra in oA-Ln₂O₂S are directed antiparallel to each other along the polar *c* axis, leading to weakening of the SHG response. Actually, the dipole moment induced by external electric field also plays a significant role in the SHG response, and thus these perturbation term should be considered to explain the observed magnitude of SHG and THG signals.²⁸

Materials with large THG signals are of high interest to extend the frequency conversion processes and generate directly coherent laser light in the UV region from commercially available laser sources.^{29,30} Indeed, there is nowadays a high demand for medical, chemical sensing or optical communication applications. In that context, the large THG signal observed in the oA-Ln₂O₂S compounds will require more investigation to fully characterize the NLO

$\chi^{(3)}$ coefficients of these compounds. This behavior of the oA-Ln₂O₂S oxysulfide compounds recalls the recent discovery of a large THG signals in another oxysulfide Ba₅(VO₂S₂)₂(S)₂.³¹ Moreover oxychalcogenides emerge as promising IR nonlinear optical (NLO) materials with good balance between large SHG coefficients and high laser damage threshold.^{32,33,34} The search for new oxysulfides with NLO or other functional properties is therefore very promising. The sulfur deintercalation method described in this paper might be an interesting alternative to design such mixed anions functional materials.^{35,36}

CONCLUSION

We have demonstrated that the topochemical deintercalation of sulfur from the Ln₂O₂S₂ compounds (Ln = La, Pr, Nd) can be triggered in presence of Rb, K and Na alkali metals. The reaction leads to a metastable form of the Ln₂O₂S compounds built on [Ln₂O₂] fluorite-type (001) slabs against [Ln₂O₂] fluorite-type (111) slabs in the stable form. The process is reversible, i.e. sulfur atoms can be deintercalated and reintercalated, and is based only on the anionic redox activity of sulfurs, i.e. the (S₂)²⁻/S²⁻ redox couple. The new topochemical Ln₂O₂S materials are non-centrosymmetric compounds. They evidence a SHG signature, but also a (very) strong THG signal. This opens the door of topochemical route to design nonlinear optical, oxysulfide materials for future applicability in optics.
