**Abstract.** We present direct measurements of biogenic volatile organic compound (BVOC)-induced nitrate radical (NO<sub>3</sub>) reactivity ( $k^{\text{VOC}}$ ) through the diel cycle in the suburban, temperate forest of Rambouillet near Paris (France). The data were obtained in a 6-week summer period in 2022 as part of the Atmospheric ChemistRy Of the Suburban foreSt (ACROSS) campaign.  $k^{\text{VOC}}$  was measured in a small (700 m<sup>2</sup>) clearing mainly at a height of 5.5 m above ground level but also at 40 m (for 5 d and nights). At nighttime, mean values (and 25th–75th percentile ranges) of  $k_{\text{night}}^{\text{VOC}}(5.5\text{ m}) = (0.24_{-0.06}^{+0.32})\text{ s}^{-1}$  and  $k_{\text{night}}^{\text{VOC}}(40\text{ m}) = (0.016_{-0.007}^{+0.018})\text{ s}^{-1}$  indicate a significant vertical gradient and low NO<sub>3</sub> reactivity above the canopy, whereas  $k_{\text{night}}^{\text{VOC}}(5.5\text{ m})$  showed peak values of up to  $2\text{ s}^{-1}$  close to the ground. The strong vertical gradient in NO<sub>3</sub> reactivity could be confirmed by measurements between 0 and 24 m on one particular night characterized by a strong temperature inversion and is a result of the decoupling of air masses aloft from the ground- and canopy-level sources of BVOCs (and nitric oxide, NO). No strong vertical gradient was observed in the mean daytime NO<sub>3</sub> reactivity, with  $k_{\text{day}}^{\text{VOC}}(5.5\text{ m}) = (0.12 \pm 0.04)\text{ s}^{-1}$  for the entire campaign and  $k_{\text{day}}^{\text{VOC}}(40\text{ m}) = (0.07 \pm 0.02)\text{ s}^{-1}$  during the 5 d period.

Within the clearing, the fractional contribution of VOCs to the total NO<sub>3</sub> loss rate coefficient ( $k^{\text{tot}}$ , determined by photolysis, reaction with NO and VOCs) was 80 %–90 % during the night and ~ 50 % during the day. In terms of chemical losses of  $\alpha$ -pinene below canopy height in the clearing, we find that at nighttime hydroxyl radicals (OH) and ozone (O<sub>3</sub>) dominate, with NO<sub>3</sub> contributing “only” 17 %, which decreases further to 8.5 % during the day. Based on measured OH, measured O<sub>3</sub>, and calculated NO<sub>3</sub> concentrations, the chemical lifetime of BVOCs at noon is about 1 h and is likely to be longer than timescales of transport out of the canopy (typically of the order of minutes), thus significantly reducing the importance of daytime in-canopy processing. Clearly, in forested regions where sufficient nitric oxide and nitrogen dioxide (NO<sub>x</sub>) is available, the role of NO<sub>3</sub> and OH as initiators of BVOC oxidation is not strictly limited to nighttime and daytime, respectively, as often implied in e.g. atmospheric chemistry textbooks.

## 1 Introduction

Forests emit great quantities ( $\sim 1000 \text{ Tgyr}^{-1}$ ) of a variety of biogenic volatile organic compounds (BVOCs), such as isoprene and monoterpenes, into the atmosphere (Guenther et al., 2012; Hakola et al., 2012; Vermeuel et al., 2023). The transport of combustion-related emissions from urban and industrialized regions results in the presence of NO<sub>x</sub> (the sum of nitric oxide, NO, and nitrogen dioxide, NO<sub>2</sub>) in forested regions, as does microbial activity in soils (Ludwig et al., 2001; Barger et al., 2005; Pilegaard, 2013). An important step in photochemical ozone (O<sub>3</sub>) generation is the oxidation of VOCs, which may be initiated by hydroxyl (OH) and nitrate radicals (NO<sub>3</sub>) or O<sub>3</sub> itself (Geyer et al., 2001; Lelieveld et al., 2008; Per  kyl   et al., 2014). The interaction of largely anthropogenic NO<sub>x</sub> with BVOCs is thus a key component of tropospheric ozone production in many regions (Pusede et al., 2015). Here we focus on NO<sub>3</sub>, which is formed from the reaction between NO<sub>2</sub> (e.g. from Reaction R1) and O<sub>3</sub> (Reaction R2) and is in a thermal equilibrium with NO<sub>2</sub> and dinitrogen pentoxide (N<sub>2</sub>O<sub>5</sub>, Reactions R3 and R4) (Wayne et al., 1991).

In the troposphere, NO<sub>3</sub> reacts efficiently with NO to re-form NO<sub>2</sub> (Reaction R5), reacts with unsaturated VOCs (Reaction R6), and is photolysed rapidly with a lifetime that is often only a few seconds (Reactions R7a and R7b) (Finlayson-Pitts and Pitts, 2000). NO is reduced in concentration at night owing to its reaction with O<sub>3</sub>, and since both NO and sunlight drastically reduce the lifetime of NO<sub>3</sub>, the latter is often thought of as a “nighttime-only” oxidant (Wayne et al., 1991; Platt and Heintz, 1994; Martinez et al., 2000; Brown and Stutz, 2012). Note that, in some environments, direct heterogeneous losses of NO<sub>3</sub>, as well as indirect losses via N<sub>2</sub>O<sub>5</sub> uptake, can also be important (Saathoff et al., 2001; Bertram and Thornton, 2009; Phillips et al., 2016).

While both the reaction with NO (Reaction R5) and the photolysis (Reaction R7) recycle either NO or NO<sub>2</sub>, reactions between NO<sub>3</sub> and VOCs result in a variety of gas-phase products, including organic nitrates (RONO<sub>2</sub>) and nitric acid (HNO<sub>3</sub>) (Hallquist et al., 1999; Ayres et al., 2015; Ng et al., 2017), which may be lost by deposition and/or trans-

ferred to the condensed phase, forming e.g. secondary organic aerosols (SOAs) (Bates et al., 2022; Day et al., 2022; DeVault et al., 2022). The interaction of NO<sub>3</sub> with BVOCs can represent an efficient process for the removal of NO<sub>x</sub> from the gas phase and a mechanism for SOA generation (Fry et al., 2014; Romer Present et al., 2020), making the fractional contribution of Reaction (R6) to the overall loss rate of NO<sub>3</sub> of particular interest.

As unsaturated BVOCs, such as isoprene and monoterpenes, are often present at part per billion by volume (ppbv) levels in the forest (Kesselmeier and Staudt, 1999; Hakola et al., 2009), the local NO<sub>3</sub> lifetimes are typically short not only during the day, but also at night (McLaren et al., 2004; J. Liebmann et al., 2018; J. M. Liebmann et al., 2018). NO<sub>3</sub> mixing ratios are often below 1 part per trillion by volume (pptv), making their detection in highly reactive air masses very challenging (J. Liebmann et al., 2018). Measuring the NO<sub>3</sub> reactivity (together with NO<sub>2</sub> and O<sub>3</sub> to calculate the NO<sub>3</sub> production rate) provides a means to assess the atmospheric fate of the nitrate radical even when its mixing ratio is too low ( $< 0.5 \text{ pptv}$ ) to be detected (Dewald et al., 2022).

There are also meteorological effects that induce differences in the fate of NO<sub>3</sub> during the day and night. While daytime insolation at ground level can result in efficient (turbulent) mixing of the boundary layer, the radiative cooling of the ground at lower temperatures at night means that the nocturnal boundary layer can be highly stratified (Stull, 1988). This results in strong gradients in the mixing ratios of e.g. BVOCs (Fish et al., 1999), and the below-canopy reactivity of NO<sub>3</sub> can be very different to that above (Mogensen et al., 2015; J. Liebmann et al., 2018). To date, NO<sub>3</sub> vertical profiles are available for high altitudes (i.e. above the boundary layer) in non-forested environments (Smith et al., 1993; von Friedeburg et al., 2002; Stutz et al., 2004; Brown et al., 2007a; Yan et al., 2021), yet highly resolved vertical profiles of NO<sub>3</sub> (or its reactivity) for low altitudes at nighttime are sparse (Brown et al., 2007b; J. Liebmann et al., 2018).

In this study, we present and analyse nighttime and daytime NO<sub>3</sub> reactivity measurements above and below the canopy in a temperate forest ca. 50 km from Paris (France) during the summer of 2022 as part of the Atmospheric ChemistRy Of the Suburban foreSt (ACROSS) campaign (Cantrell and Michoud, 2022).

## 2 Experimental

### 2.1 Site description and meteorology

The ACROSS campaign took place from mid-June until the end of July 2022 at a clearing (ca. 700 m<sup>2</sup>) in the suburban forest of Rambouillet in France (48.687   N, 1.704   E). Rambouillet forest covers an area of about 150 km<sup>2</sup> and is located about 50 km to the south-west of Paris. The surrounding trees are mainly oaks ( $\sim 68 \%$ ) and pine (up to

25 %) (Marchant et al., 2017), with an average height of  $\sim 25$  m. Daytime maximum temperatures during ACROSS were  $\sim 20$ – $40^\circ\text{C}$  (Fig. 1b), while nighttime temperatures decreased to  $10$ – $25^\circ\text{C}$ , often with a significant (positive) gradient in height that started to develop in the late afternoon when tree-induced shadowing of the ground led to radiative cooling (Andersen et al., 2024).

Back trajectories of 48 h show that air originated from the Atlantic Ocean between 25 June and 2 July, whereas air passed predominantly over industrialized regions, including Paris, the UK, Benelux states, and the Ruhr area, from 2–18 July (Andersen et al., 2024). Local wind directions and speeds are shown as a wind rose in the Supplement (Fig. S1).

The clearing housed several instrumented containers and also a tower, which enabled measurements to be made at 40 m, either via instruments located at the top of the tower or via sampling from a gas manifold attached to a high-flow inlet at the top of the tower.

## 2.2 $\text{NO}_3$ reactivity

The flow-tube cavity ring-down spectrometer (FT-CRDS; Liebmann et al., 2017) used to quantify  $\text{NO}_3$  reactivity was installed in the Max Planck Institute for Chemistry (MPIC) container and sampled mainly from the centre of a high-volume-flow ( $10\,000$  standard  $\text{L min}^{-1}$ , slpm) stainless steel tube ( $\varnothing = 15$  cm), the top of which was 5.5 m above ground level (m a.g.l.). We present measurements of  $k^{\text{VOC}}$ , which is defined as the VOC-induced pseudo-first-order  $\text{NO}_3$  loss rate coefficient (in units of  $\text{s}^{-1}$ ) and is equal to  $\sum k_i[\text{VOC}]_i$ , with  $[\text{VOC}]_i$  and  $k_i$  being the VOC concentrations and the corresponding rate coefficient for Reaction (R6), respectively. The FT-CRDS was connected to the high-flow inlet with a 1.5 m long piece of 1/4 in. outer diameter (o.d.) PFA tubing (overall residence time of 0.4 s) equipped with a Teflon membrane filter (2  $\mu\text{m}$  pore, 47 mm diameter, Pall Corp.) to prevent particles entering the cavity. The filter was replaced every 3 d. From 18 July, the  $\text{NO}_3$  reactivity setup sampled air alternately from the high-flow inlet and from the manifold, taking air from 40 m. The instrument was attached to the manifold with ca. 20 m 1/4 in. PFA tubing (ca. 5 s residence time).

$\text{NO}_3$  was generated by mixing  $3$ – $5$  standard  $\text{cm}^3 \text{min}^{-1}$  (sccm) of NO (1 part per million by volume (ppmv) in  $\text{N}_2$ , Air Liquide) with  $\text{O}_3$  in a thermostated ( $30^\circ\text{C}$ ) Teflon-coated (FEPD 121, Chemours) reactor (ca. 5 min residence time) at a pressure of 1100 Torr.  $\text{O}_3$  was generated by the 185 nm photolysis of  $\text{O}_2$  in a flow of 400 sccm dry synthetic air, which was provided from a commercial zero-air generator (CAP-180, Fuhr GmbH). In order to convert the resultant  $\text{N}_2\text{O}_5$  quantitatively to  $\text{NO}_3$  (Reaction R4), the flow was heated to  $140^\circ\text{C}$  in ca. 15 cm of 1/4 in. o.d. PFA tubing. The flow containing  $\text{NO}_3$  was then mixed with 2.8 slpm of either synthetic air (to define zero reactivity) or ambient air within a 1/4 in. PFA T-piece and directed to the FEP-coated, dark-

ened, and thermostated ( $20^\circ\text{C}$ ) flow tube where  $\text{NO}_3$  had 11 s to react.  $\text{NO}_3$  surviving the reactor was quantified online by cavity ring-down spectroscopy at 662 nm. Zeroing (“baseline measurement”) was achieved by adding an excess of NO (3 sccm of 100 ppmv in  $\text{N}_2$ , Air Liquide) to titrate  $\text{NO}_3$  (Reaction R5). In synthetic air, the  $\text{NO}_3$  mixing ratios were typically in the range of 30–50 pptv. As the presence of  $\text{NO}_3$  and  $\text{N}_2\text{O}_5$  in ambient air would bias the measurement, at nighttime the air was sampled through a 2 L glass flask (heated to  $35^\circ\text{C}$ ,  $\sim 40$  s residence time) to ensure that ambient  $\text{N}_2\text{O}_5$  is converted to  $\text{NO}_3$ . All radicals, including  $\text{NO}_3$ , OH,  $\text{RO}_2$ , and  $\text{HO}_2$ , are lost on the glass walls and thus prevented from reaching the flow tube. From 18 July, air was sampled through the glass flask throughout the diel cycle. No difference in  $k^{\text{VOC}}$  was observed directly after switching between “daytime mode” (no flask) and “nighttime mode” (sampling through flask), indicating that no compounds significantly contributing to  $k^{\text{VOC}}$  are lost in the glass flask. Accurate quantification of  $\text{NO}_3$  reactivity requires that the synthetic air is humidified to ambient level (monitored with a commercial sensor, IST, HYT939), which was achieved with a permeation tube (MH-070-24F-4, Perma Pure LLC) filled with de-ionized water (LiChrosolv, Merck GmbH). Dynamic dilution of ambient air with synthetic air extended the dynamic range of the instrument to  $\text{NO}_3$  reactivities of up to ca.  $2.1 \text{ s}^{-1}$ . Since Reactions (R1) to (R5) and wall losses ( $0.001 \text{ s}^{-1}$ ) take place in addition to the reaction of interest (Reaction R6), a numerical simulation procedure was used to separate contributions of  $\text{NO}_x$  in the flow tube and thus extract the  $\text{NO}_3$  reactivity towards VOCs, as detailed in Liebmann et al. (2017). When sampling through the glass flask, ambient NO mixing ratios used for the simulation were corrected for the impact of Reaction (R1) with correction factors between 1 % and 40 %.

The uncertainty in  $k^{\text{VOC}}$  is determined by the stability of the  $\text{NO}_3$  source, the cavity stability (i.e. noise level and baseline stability), and the numerical simulation corrections. The uncertainty induced by the simulation is dependent on the ratio between  $\text{NO}_2$  and  $k^{\text{VOC}}$  (Liebmann et al., 2017). During the campaign source and cavity stability, numerical simulation and uncertainties in the NO correction (impact of Reaction R5) contributed on average ca. 11 %, 9 %, and 26 % to the average overall uncertainty of ca. 30 %. The limit of detection (LOD) is derived from the variability (2 standard deviations,  $2\sigma$ ) in consecutive baselines and  $\text{NO}_3$  source measurements and was on average  $0.006 \text{ s}^{-1}$  during this campaign. In this paper we index the  $\text{NO}_3$  reactivity according to the following scheme:  $k_{\text{night}}^{\text{VOC}}(5.5 \text{ m})$ ,  $k_{\text{day}}^{\text{VOC}}(5.5 \text{ m})$ ,  $k_{\text{night}}^{\text{VOC}}(40 \text{ m})$ , and  $k_{\text{day}}^{\text{VOC}}(40 \text{ m})$ , which are the measured reactivities towards VOCs during the day/night at the two different heights. Note that reactivity measurements at 40 m were limited to the last 5 d of the campaign. We also refer to  $k^{\text{tot}}$ , which is the total  $\text{NO}_3$  loss term including reaction with NO and photolysis as well as reaction with VOCs.

**Figure 1.** Time series of  $\text{NO}_3$  photolysis frequencies ( $J_{\text{NO}_3}$ , **a**), temperature ( $T$ , **b**), ozone ( $\text{O}_3$ , **c**), nitrogen dioxide ( $\text{NO}_2$ , **d**), nitric oxide ( $\text{NO}$ , **e**), and VOC-induced  $\text{NO}_3$  reactivity ( $k^{\text{VOC}}$ , **f**) sampled at 5.5 m a.g.l. (orange triangles; 3.2 and 5 m for  $\text{NO}$  and  $T$ , respectively) and 40 m a.g.l. (blue circles). The major and minor ticks on the  $x$  axis represent 00:00 UTC of the corresponding date. The dashed lines separate periods with air of Atlantic and continental origin. Nighttime periods are grey-shaded.

### 2.3 $\text{NO}$ , $\text{NO}_2$ , and $\text{O}_3$

$\text{NO}_2$  mixing ratios at 5.5 m were measured by sampling via 1.5 m 1/4 in. (o.d.) PFA tubing and a membrane filter (2  $\mu\text{m}$  pore, 47 mm diameter, Pall Corp.) through the second (405 nm) cavity of the  $\text{NO}_3$  reactivity instrument (J. M. Liebmann et al., 2018). The instrument's LOD was 87 pptv ( $2\sigma$ , 4 s), and the measurement was associated with a total uncertainty of 7 %. On top of the tower (40 m),  $\text{NO}_2$  was measured via a cavity attenuated phase shift (CAPS) setup (precision of 6 %, LOD of 40 pptv), which was zeroed on an hourly basis.

$\text{NO}$  was measured using a commercial instrument based on chemiluminescence detection (CLD 780 TR, Eco Physics, LOD of 10 pptv for 1 min averaging time), which was installed in a container ca. 17 m distance from the MPIC container and sampled at a height of 3.2 m above the ground.

The  $\text{NO}$  mixing ratios were corrected for a change in sensitivity during the campaign (Andersen et al., 2024). Measurement of  $\text{NO}$  at 40 m height was carried out using another CLD (T200UP, Teledyne) that sampled from the tower manifold. This measurement was corrected for losses from Reaction (R1), with corrections ranging from 1 %–28 %. The instrument's LOD was 30 pptv, and its total uncertainty was 3.2 %.

A commercial ozone monitor (model 205, 2B Technologies) based on UV absorption was installed in the MPIC container and measured ozone mixing ratios at 5.5 m height with an LOD of 2 ppbv and an associated uncertainty of 5 %.  $\text{O}_3$  from the top of the tower was quantified by means of a second ozone monitor with an LOD of 2.5 ppbv (APOA370, HORIBA).

## 2.4 Photolysis frequencies and temperatures

Actinic flux was measured on top of the tower (41 m) and above the roof of the MPIC container (5 m), in both cases using spectral radiometers (Metcon GmbH). Actinic fluxes were converted to photolysis frequencies of NO<sub>3</sub> and other compounds using IUPAC- and NASA-evaluated absorption cross sections (Burkholder et al., 2016; IUPAC, 2024). Commercial temperature sensors (Atexis PT1000 and Thermoset PT100) monitored ambient air temperature simultaneously at 5, 13, 21, and 41 m.

## 3 Results and discussion

An overview of the measurements relevant for analysis of NO<sub>3</sub> reactivity is given in Fig. 1 where data obtained at 5.5 m a.g.l. (orange) and 40 m a.g.l. (blue) are plotted.

The VOC-induced NO<sub>3</sub> reactivity at a height of 5.5 m ( $k^{\text{VOC}}(5.5\text{ m})$ , panel f, orange triangles) was generally high, with values between  $\sim 0.1$  and  $0.5\text{ s}^{-1}$ , and also highly variable, with nighttime peak values of up to  $2\text{ s}^{-1}$ . In contrast,  $k^{\text{VOC}}_{\text{night}}(40\text{ m})$  was often close to or below the LOD ( $\leq 0.006\text{ s}^{-1}$ ) when sampling from the top of the tower between 18 and 23 July (panel f, blue circles).

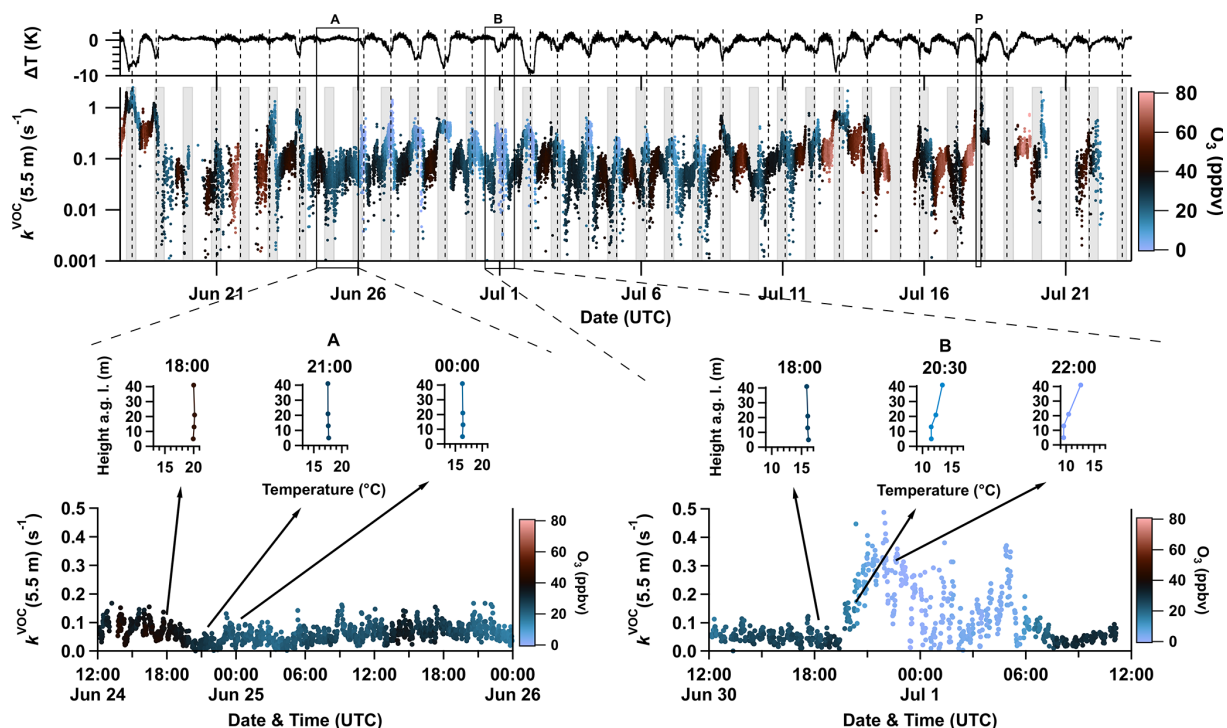

NO mixing ratios (panel e) at 3.2 m a.g.l. (orange circles) were on average between 0.1 and 0.3 ppbv but occasionally peaked at 1–4 ppbv mostly in the morning during the continental phase. As detailed in Andersen et al. (2024), nighttime NO mixing ratios were close to or below the LOD when sampling air masses, which, according to 2 d back trajectories, were largely of continental origin (2–18 July). In contrast, up to several parts per billion by volume of NO were observed at night during a period dominated by air with its origin over the Atlantic (26 June–2 July) when O<sub>3</sub> levels (at 5.5 m) were below the LOD (panel c). NO<sub>2</sub> mixing ratios (panel d) were similar at both heights and, in the absence of anthropogenic influence, mostly between 0.5 and 2 ppbv.

The large diel variation in O<sub>3</sub> mixing ratios at 5.5 m (40–80 ppbv during the day and as low as 0 at nighttime, panel c) results from its net daytime photochemical production through reactions involving OH, NO<sub>x</sub>, and VOCs (Crutzen and Lelieveld, 2001) and its nocturnal losses via reactions (e.g. with NO and BVOC) and deposition. Nocturnal O<sub>3</sub> mixing ratios at 40 m (20–40 ppbv) are higher than at 5.5 m (0–20 ppbv), and their diel cycle at 40 m is weaker than at 5.5 m. This results from a combination of removal processes of O<sub>3</sub> at lower levels (reaction with NO released from soil, reaction with unsaturated, biogenic VOCs released from vegetation, and deposition to soil and foliar surfaces) and weak vertical mixing at nighttime (Andersen et al., 2024).

## 3.1 $k^{\text{VOC}}$ : variability and controlling factors close to the ground

At a height of 5.5 m,  $k^{\text{VOC}}$  shows large variability across the diel cycle and from night-to-night (Fig. 1f), which is driven by variability in emissions of reactive BVOCs and in the height of the nocturnal boundary layer (NBL). In Fig. 2,  $k^{\text{VOC}}(5.5\text{ m})$  is plotted together with the difference in temperature ( $\Delta T$ ) measured at 5 and 41 m, where  $\Delta T = T(5\text{ m}) - T(41\text{ m})$ , and shows that the largest values of  $k^{\text{VOC}}_{\text{night}}(5.5\text{ m})$  occur on nights when a temperature inversion ( $\Delta T < 0\text{ K}$ ) evolves. The impact of temperature inversion on NO<sub>3</sub> reactivity at 5.5 m is illustrated by comparing a night with no temperature inversion (24–25 July, period A) to a night with moderate temperature inversion (30 June–1 July, period B). In the absence of a temperature inversion we see a roughly constant value  $< 0.1\text{ s}^{-1}$  for  $k^{\text{VOC}}(5.5\text{ m})$  through the diel cycle (period A in the inset of Fig. 2). In contrast, when a temperature inversion developed (period B in the inset of Fig. 2),  $k^{\text{VOC}}(5.5\text{ m})$  was relatively low ( $< 0.1\text{ s}^{-1}$ ) until ca. 19:30 UTC. Over the next 2 h, it gradually increased to reach peak values as large as  $0.4\text{ s}^{-1}$ , which were associated with larger variability. Over the same period, O<sub>3</sub> levels decreased from  $\sim 30$ –40 to  $< 10$  ppbv, which has been rationalized in terms of suppression of entrainment of above-canopy air (with higher levels of O<sub>3</sub>) into air masses close to the ground during temperature inversions (Andersen et al., 2024). The temperature inversion and associated reduction in vertical mixing impede upward transport of both NO (emitted from the soil) and BVOCs (emitted from vegetation) so that both may accumulate within and below the canopy after sunset. The association of high values of  $k^{\text{VOC}}(5.5\text{ m})$  with low values of O<sub>3</sub> during nighttime temperature inversions has previously been reported for the boreal forest (J. Liebmann et al., 2018). In addition, elevated NO<sub>3</sub> reactivity at night is also aided by the fact that the nocturnal mixing ratios of O<sub>3</sub> and OH are diminished due to deposition and/or lack of photochemistry so that the lifetime and mixing ratios of monoterpenes increase (see Sect. 3.6).

The hypothesis that temperature inversions partially drive the observed NO<sub>3</sub> reactivity within the canopy is reinforced by close inspection of the temperature profiles in period B in the inset of Fig. 2. At 18:00 UTC, no gradient in temperature ( $16.5^\circ\text{C}$ ) between 5 and 41 m was observed. At 20:30 UTC, a positive gradient in temperature was observed at heights  $> 20\text{ m}$ , becoming more distinct at 22:00 UTC. Under these conditions, vertical mixing from ground level to above-canopy levels (ca. 20 m) is suppressed, whereas some mixing may still take place between 5 and 13 m where no temperature difference was observed. Weak (but non-zero) vertical mixing at the lower levels may be the cause of the high variability in  $k^{\text{VOC}}_{\text{night}}(5.5\text{ m})$  whereby instabilities in the stratification at lower levels of the NBL allow for sampling (at 5.5 m) of air with different (variable) time periods spent at lower/higher levels and thus with highly variable reactiv-

**Figure 2.** Time series of  $k^{\text{VOC}}$  (second panel, logarithmic scale) near ground level (5.5 m) coloured by  $\text{O}_3$  mixing ratios measured at the same height (colour scale on the right). Nighttime periods are grey-shaded. The difference between temperatures measured at 5 and 41 m ( $\Delta T$ ) is plotted in the first panel. Temperature inversions are marked by dashed vertical lines. Periods A (lower-left panel) and B (lower-right panel) exemplify daytime–nighttime transitions, both with (right) and without (left) clear temperature inversions, with  $\text{NO}_3$  reactivity plotted along with temperature profiles at selected times. A vertical profile of  $k^{\text{VOC}}$  was measured in period P (see Sect. 3.5).

ity. The resulting high variability in  $\text{NO}_3$  mixing ratios has been documented for  $\text{NO}_3$  measurements made close to the ground (Brown et al., 2003; Crowley et al., 2010).

In forests, the most abundant BVOCs are typically isoprene and monoterpenes (Hakola et al., 2012; Vermeuel et al., 2023). Since the corresponding rate coefficients for the reaction of  $\text{NO}_3$  with monoterpenes are up to 2 orders of magnitude larger than those of isoprene (IUPAC, 2024), monoterpenes are expected to be the main contributor to  $k^{\text{VOC}}$  during the ACROSS campaign. Relative monoterpene emission factors are temperature dependent and described by  $\exp(\beta(T - 297 \text{ K}))$  with  $\beta = 0.1 \text{ K}^{-1}$  in forested environments (Guenther et al., 1993), resulting in a strong seasonal variation (Hakola et al., 2006; Vermeuel et al., 2023). As a consequence, correlations between air temperature, VOC mixing ratios, and OH reactivity have been reported (Kalogridis et al., 2014; Pfannerstill et al., 2021). Figure 3a shows that, during the day (black data points), with temperatures varying from 297 to 311 K, an increase in  $k^{\text{VOC}}(5.5 \text{ m})$  is observed. The inset contains daytime values measured between 10:00 and 14:00 UTC against air temperature, and a linear regression suggests a fair correlation between the two (Pearson correlation coefficient  $r = 0.66$ ). The factor of 4 increase in the emission rate over this range as reported in Guenther et al. (1993) is much larger than the observed change in

$k^{\text{VOC}}(5.5 \text{ m})$ . This is however expected as the daytime concentrations of monoterpenes (MTs) will be determined not only by emission rates but also by their lifetime, which, in the clearing, will be reduced by reactions with daytime oxidants such as OH and  $\text{O}_3$  and (possibly more importantly) transport out of the canopy (Bohn, 2006). At nighttime (blue and red dots in Fig. 3a), there is no clear correlation between  $k^{\text{VOC}}(5.5 \text{ m})$  and temperature, although the highest values of  $k^{\text{VOC}}(5.5 \text{ m})$  are generally observed at lower temperatures. A plot of  $k^{\text{VOC}}_{\text{night}}(5.5 \text{ m})$  versus  $\Delta T$ , coloured according to the temperature at 5 m (Fig. 3b), reveals that higher  $\text{NO}_3$  reactivity is accompanied by large (negative) values of  $\Delta T$ . The maximum value of  $k^{\text{VOC}}_{\text{night}}(5.5 \text{ m}) \approx 2 \text{ s}^{-1}$  was observed when a strong temperature inversion ( $\Delta T < -6 \text{ K}$ ) coincided with a high nocturnal air temperature. During cooler nights ( $T(5 \text{ m}) < 12 \text{ }^\circ\text{C}$ ),  $k^{\text{VOC}}(5.5 \text{ m})$  was  $< 0.5 \text{ s}^{-1}$  even during periods with very strong temperature inversions. Our analysis thus shows that while temperature is an important factor influencing  $\text{NO}_3$  reactivity at 5.5 m through enhanced rates of emission of BVOCs, the effect (at least at sub-canopy levels) is greatly amplified by temperature inversions which favour accumulation of MTs in a shallow boundary layer close to the surface. In an upcoming publication we use monoterpene measurements to analyse  $\text{NO}_3$  (and  $\text{N}_2\text{O}_5$ ) mixing ratios and lifetimes at both 5.5 and 40 m heights during ACROSS and

draw a comparison between directly measured NO<sub>3</sub> reactivity and that attributed to various BVOCs.

### 3.2 Nitrate radical lifetime within and above the canopy

For the last 5 d of the ACROSS campaign (18–23 July), the NO<sub>3</sub> reactivity was measured at a height of 40 m every even hour, with data obtained at 5.5 m every odd hour. The corresponding time series of this measurement with a discussion of the vertical gradients observed during this period is appended in the Supplement (Sect. S2). With the data from this period, we could derive the total (chemical) loss rate coefficient of NO<sub>3</sub> not only at 5.5 m but also at 40 m, which is given by

$$k^{\text{tot}} \approx k^{\text{VOC}} + J_{\text{NO}_3} + k_5[\text{NO}], \quad (1)$$

where  $k^{\text{VOC}}$  is our directly measured VOC-induced loss,  $J_{\text{NO}_3} = k_{7a} + k_{7b}$  is the NO<sub>3</sub> photolysis frequency (Fig. 1a), and  $k_5$  is the rate coefficient (IUPAC, 2024) for the reaction between NO and NO<sub>3</sub>. Equation (1) neglects NO<sub>3</sub> loss processes resulting from direct (and indirect) heterogeneous reactions of NO<sub>3</sub> (and N<sub>2</sub>O<sub>5</sub>) as well as reactions with HO<sub>x</sub> and organic radicals, which, for the ACROSS environment, is justified in the Supplement (Sect. S3). The NO<sub>3</sub> lifetime  $\tau_{\text{NO}_3}$  is the inverse of the total NO<sub>3</sub> loss rate coefficient:

$$\tau_{\text{NO}_3} = 1/k^{\text{tot}}. \quad (2)$$

We plot  $\tau_{\text{NO}_3}$  through the diel cycle (5.5 and 40 m) in Fig. 4. To calculate  $k^{\text{tot}}$ (5.5 m), the whole campaign period (as in Fig. 1) was considered since data gaps in both NO and  $J_{\text{NO}_3}$  close to the ground and on top of the tower reduced the availability of quasi-simultaneous values of  $k^{\text{tot}}$ (5.5 m) and  $k^{\text{tot}}$ (40 m) (see Sect. S4). At a height of 5.5 m, the nocturnal lifetime of NO<sub>3</sub> is 2–3 s and (counterintuitively) somewhat longer (4–5 s) during the day despite its photolysis. At a height of 40 m, above the canopy, the daytime lifetime of NO<sub>3</sub> is close to 3–4 s, whereas at night it increases to 10–12 s. The similar lifetimes at both heights during the day imply a vertically well-mixed layer. On the other hand, the longer nocturnal lifetime at 40 m compared to 5.5 m can be attributed to decoupling from direct (ground-level and within-canopy) sources of NO and BVOCs (see Sect. 3.1). The longer nocturnal lifetime of NO<sub>3</sub> at 40 m enabled it to be detected on some nights of the campaign, whereas NO<sub>3</sub> measurements were, unlike N<sub>2</sub>O<sub>5</sub>, always below LOD close to the ground. A detailed analysis of the NO<sub>3</sub> (and N<sub>2</sub>O<sub>5</sub>) measurements will be presented in a future publication.

### 3.3 Fate of the nitrate radical within the canopy

A mean diel cycle of  $k^{\text{VOC}}$ (5.5 m) for the whole campaign is depicted in Fig. 5. The higher mean nighttime value ( $k_{\text{night}}^{\text{VOC}}$ (5.5 m) =  $(0.24^{+0.32}_{-0.06}) \text{ s}^{-1}$ ) compared to  $k_{\text{day}}^{\text{VOC}}$ (5.5 m) =  $(0.12 \pm 0.04) \text{ s}^{-1}$ ) is a result of the accumulation of BVOCs in a shallow sub-canopy layer with reduced

rates of canopy venting owing to temperature inversions. The observation of a daytime minimum and nighttime maximum in  $k^{\text{VOC}}$ (5.5 m) is consistent with measurements in the boreal forest in Finland (J. Liebmann et al., 2018), where terpene emissions dominated the fate of NO<sub>3</sub>, and strong temperature inversions were present at night. Values of  $k^{\text{VOC}}$  in the boreal forest in autumn were a factor of 2–3 lower than those we measured in the temperate forest during ACROSS, which is presumably related to the lower temperatures as well as other factors such as leaf area index, vegetation type, and availability of oxidizing agents, which affect the abundance of monoterpenes.

The fractional contribution,  $F^{\text{VOC}}$ , of the reaction of NO<sub>3</sub> with VOCs to its total loss rate coefficient,  $k^{\text{tot}}$ , is given by Eq. (3):

$$F^{\text{VOC}} = k^{\text{VOC}}/k^{\text{tot}} \quad (3)$$

and shown in Fig. 5. At night,  $F^{\text{VOC}}$  (grey-shaded area, blue line) is ca. 0.7–0.8, with the remaining 20 % to 30 % assigned to reaction with NO. During the day, while photolysis (20 %) and reaction with NO (30 %) gain increased importance, VOCs still account for 50 % of the NO<sub>3</sub> reactivity. The large daytime contribution of  $k^{\text{VOC}}$  is partly related to the fact that actinic flux (and thus the photolysis frequencies of NO<sub>3</sub>) within the clearing at 5.5 m height is reduced compared to above-canopy levels (Fig. 1a). In addition, the photolysis frequency for NO<sub>2</sub> is also reduced so that the distribution of NO<sub>x</sub> between NO and NO<sub>2</sub> is shifted towards NO<sub>2</sub> and away from NO, resulting in a reduction in  $k_5[\text{NO}]$ . In order to assess the impact of this effect, we calculated  $F^{\text{VOC}}$  with above-canopy values of  $J_{\text{NO}_3}$  and NO. In this scenario, daytime  $F^{\text{VOC}}$  increases to 33 %; i.e. the reduction in photolysis frequencies increases  $F^{\text{VOC}}$  by a factor of 1.5. J. Liebmann et al. (2018) reported a daytime average for  $F^{\text{VOC}}$  of only 20 % in a boreal forest. Despite the fact that both sites are similarly affected by low NO and high monoterpene levels, this value is still significantly lower than 33 %, which can be reconciled with lower daytime values of  $k^{\text{VOC}}$  in the boreal forest. The comparatively high daytime contribution of VOCs to NO<sub>3</sub> consumption below the canopy thus stems from both reduction in  $J_{\text{NO}_3}$  and higher values of  $k^{\text{VOC}}$ , with the latter most likely due to higher concentrations of monoterpenes than in the boreal forest. This observation is consistent with even higher daytime VOC contributions to NO<sub>3</sub> loss of > 97 % reported for sunlit wildfire plumes by Decker et al. (2021), who reconciled their result with VOC mixing ratios that were sufficiently high to outcompete photolysis and NO.

We note at this point that the photolysis frequencies measured in the clearing will be substantially larger than in the non-cleared forest. By comparing  $J_{\text{NO}_3}$ (5.5 m) with values observed above the canopy in the early morning and afternoon when the integrating dome of the spectral radiometer experienced only diffuse sunlight, we observe a reduction in  $J_{\text{NO}_3}$ (5.5 m) by a factor of > 10 (Sect. S5). A substantial reduction in in-forest actinic flux compared to in a clearing and

**Figure 3.** (a)  $\text{NO}_3$  reactivity at 5.5 m ( $k^{\text{VOC}}(5.5 \text{ m})$ ) plotted against the expected change in the monoterpene emission factor ( $E_{\text{MT}}$ ) relative to 297 K using  $E_{\text{MT}} \propto \exp(0.1 \text{ K}^{-1}(T - 297 \text{ K}))$  (Guenther et al., 1993). Data points are coloured according to the time of the day (UTC) with night/morning (blue), daytime (black), and afternoon/night (red). The inset shows  $k^{\text{VOC}}(5.5 \text{ m})$  between 10:00 and 14:00 UTC plotted against air temperature (5 m). Linear regression (solid blue line) yields a Pearson correlation coefficient ( $r$ ) of 0.66. (b) Nocturnal ground-level  $\text{NO}_3$  reactivity  $k^{\text{VOC}}_{\text{night}}(5.5 \text{ m})$  versus the temperature difference ( $\Delta T$ ) between 41 and 5 m. The data points are coloured according to the ground-level temperature  $T(5 \text{ m})$ .

**Figure 4.** Mean diel cycle of overall  $\text{NO}_3$  lifetime ( $\tau_{\text{NO}_3}$ ) calculated from Eq. (2) at 5.5 m (dark orange triangles with solid line, 17 June–23 July) and 40 m (blue circles with dashed line, every 2 h, 18–23 July). The shaded areas represent the standard deviation ( $1\sigma$ ). The nighttime period (19:30 to 03:30 UTC) is grey-shaded.

above the canopy has been reported by Bohn (2006) for a temperate deciduous forest, albeit of different tree type and density of foliage. As discussed by Bohn (2006), a reduction

in  $\text{NO}_3$  photolysis frequency implies that the relative importance of  $\text{NO}_3$  (compared to OH and  $\text{O}_3$ ) as a daytime oxidant in the forest canopy is even larger than that ( $\sim 50\%$ ) derived above. A caveat to this is that the formation of  $\text{NO}_3$  requires the presence of  $\text{O}_3$  and  $\text{NO}_2$ , both of which are likely to have substantial deposition terms in dense foliage in the non-cleared forest. We also recognize that, during the daytime, the in-canopy chemical lifetimes of BVOCs may be much longer (see Sect. 3.6) than the average residence time with respect to canopy outflow so that most BVOC daytime oxidation may take place above the forest.

### 3.4 Fate of the nitrate radical above the canopy

In Fig. 6, we plot the diel cycle of  $k^{\text{VOC}}(40 \text{ m})$ , which shows a daytime maximum and nighttime minimum, which is the opposite of that measured at 5.5 m (see Fig. 5) but is typical of measurement sites that are decoupled from near-ground emissions during the night (Crowley et al., 2011; J. M. Liebmann et al., 2018; Dewald et al., 2022). The daytime mean value of  $k^{\text{VOC}}_{\text{day}}(40 \text{ m}) = (0.07 \pm 0.02) \text{ s}^{-1}$  is similar to that measured at 5.5 m, which presumably re-

**Figure 5.** Mean diel profiles (10 min averages, 17 June–23 July) of VOC-induced NO<sub>3</sub> reactivity ( $k^{\text{VOC}}$ , right y axis) at 5.5 m along with its fractional contribution ( $F^{\text{VOC}}$ , left y axis) to the overall NO<sub>3</sub> loss. The shaded areas represent the standard deviation ( $1\sigma$ ). The nighttime period is grey-shaded and separated by solid black lines. The pie chart shows the fractional contribution of each process in Eq. (1) to the overall NO<sub>3</sub> loss term during the day.

**Figure 6.** Mean diel profiles (1 h averages, every 2 h, 18–23 July) of VOC-induced NO<sub>3</sub> reactivity ( $k^{\text{VOC}}$ , orange triangles) at 40 m along with its fractional contribution ( $F^{\text{VOC}}$ , blue circles) to the overall NO<sub>3</sub> loss. The shaded areas represent the standard deviation ( $1\sigma$ ). The nighttime period is grey-shaded. The pie chart shows the fractional contribution of each process in Eq. (1) to the overall NO<sub>3</sub> loss term during the day.

sults from vertical mixing that is rapid compared to chemical lifetimes of BVOCs and NO. In contrast, the average value ( $\pm 25$ th and 75th percentiles, respectively) of  $k_{\text{night}}^{\text{VOC}}(40\text{ m}) = (0.016^{+0.018}_{-0.007})\text{ s}^{-1}$  is approximately 1 order of magnitude lower than  $k_{\text{night}}^{\text{VOC}}(5.5\text{ m})$ . Recall however that due to its poor data coverage during the 5 d period,  $k^{\text{VOC}}(5.5\text{ m})$  from the whole campaign is used for this comparison.

The daytime, chemical, and gas-phase NO<sub>3</sub> loss processes at 40 m (see pie chart in Fig. 6) also differ significantly from those at 5.5 m (see Fig. 5), with the contribution of BVOCs almost halved (25.5 %) in favour of both NO (48 %) and photolysis (26.5 %). Reaction with NO is thus the main daytime loss process for NO<sub>3</sub> at 40 m, which is a result of greater NO mixing ratios at this height during the 5 d period. But even at night, NO mixing ratios during this period were still high enough (40–150 pptv) to compete with VOCs. In addition, some days between 18 and 23 July were cloudy, which is why NO<sub>3</sub> loss via reaction with NO prevails even at a height of 40 m. A time series comparing  $J_{\text{NO}_3}$ ,  $k_5[\text{NO}]$ , and  $k^{\text{tot}}$  at both heights during this period is appended in the Supplement (Sect. S4).

### 3.5 Vertical gradient (0–24 m) in NO<sub>3</sub> reactivity

During the night from 17–18 July (a night with a strong temperature inversion with  $\Delta T$  between  $-4$  and  $-6$  K), gas-phase NO<sub>3</sub> reactivity (resulting from reaction with both BVOCs and NO), NO<sub>2</sub>, and O<sub>3</sub> were measured at heights between 0 and 24 m a.g.l. in 4 m steps. Measurements of NO<sub>2</sub> and O<sub>3</sub> at 40 m during the same night are also plotted in Fig. 7. As NO mixing ratios were not available at all heights, the NO<sub>3</sub> reactivity was not corrected for this and thus includes NO<sub>3</sub> removal via reaction with NO ( $k^{\text{NO}} = k_5[\text{NO}]$ ); i.e.  $k^{\text{VOC}}$  becomes  $k^{\text{VOC}} + k^{\text{NO}}$ .

Between 20:00 and 00:00 UTC five profiles of  $k^{\text{VOC}} + k^{\text{NO}}$  were measured, each taking  $< 20$  min. The first profile was measured after an increase in  $k_{\text{night}}^{\text{VOC}}(5.5\text{ m})$ , which was associated with the onset of the temperature inversion.  $k^{\text{VOC}} + k^{\text{NO}}$  (averaged over the five single profiles) is plotted against height in Fig. 7c along with the data obtained at 40 m in the following nights (see Sect. 3.2). The data reveal a strong trend in NO<sub>3</sub> reactivity, with the highest values ( $0.34\text{ s}^{-1}$ ) measured at ground level, where NO is expected to have a greater impact, gradually decreasing with height to a value of ca.  $0.08\text{ s}^{-1}$  at 24 m. The data at 40 m (uncorrected for NO) are broadly consistent with this trend and, together with Fig. 6, imply that NO is the main contributor to NO<sub>3</sub> reactivity above canopy level. The gradient in NO<sub>2</sub> (Fig. 7b) shows no clear trend for heights below 24 m and is determined by its nighttime production (mainly the reaction between NO and O<sub>3</sub>), which depends on the availability of NO and the availability of O<sub>3</sub> (which has a positive gradient). As modelled in Stutz et al. (2004), a negative nocturnal gradient in NO with height is expected, notably due to soil emission and reaction with O<sub>3</sub> (Andersen et al., 2024). In addition, NO<sub>2</sub> loss via deposition is expected to be more important at the lower levels. These processes appear to roughly counterbalance each other on this night, resulting in an almost-constant mixing ratio between ground level and 24 m. This observation is consistent with that in Stutz et al. (2004), who could, if at all, only find very weak gradients. Figure 7a also includes the vertical profiles of O<sub>3</sub>, which increases from ca.

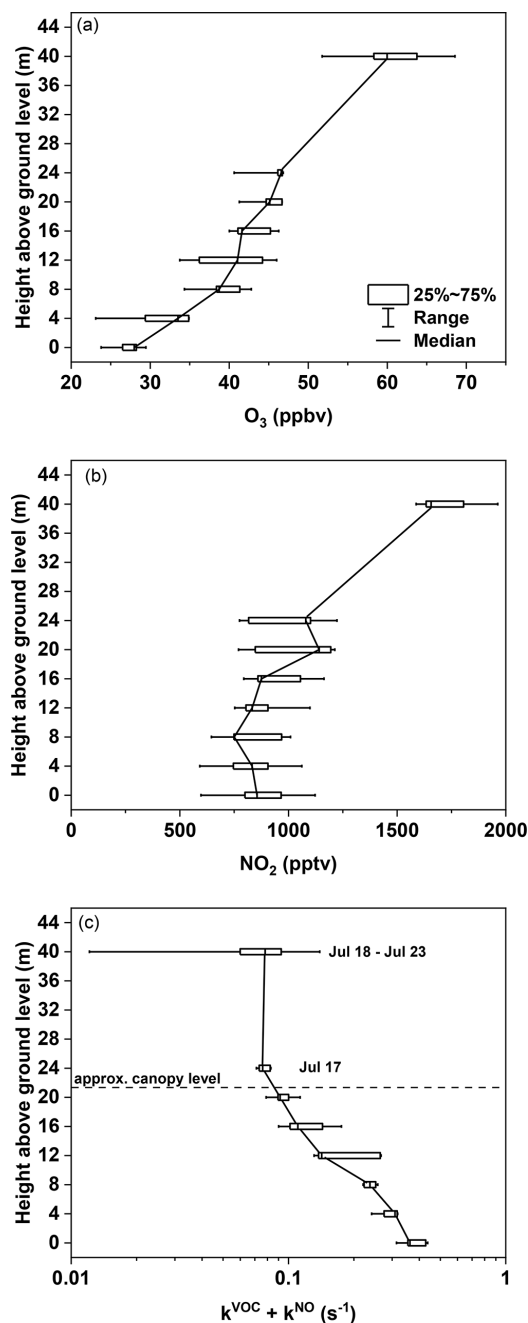

27 ppbv at ground level to 58 ppbv at 40 m, presumably a result of near-ground loss processes such as deposition and reaction with NO/BVOCs and lack of entrainment of O<sub>3</sub> from above the canopy, where higher mixing ratios were measured (Fig. 1c) (Brown et al., 2007a). The measured vertical profiles of O<sub>3</sub> were much less distinct in Stutz et al. (2004), which contradicted their model calculations that suggested a monotonic increase within the first 100 m, broadly consistent with our case study.

### 3.6 Fractional contribution of NO<sub>3</sub> to BVOC oxidation below the canopy

Our results show that, within the canopy, the nitrate radical is lost by reactions with BVOCs not only during the night but also during the day. Here we calculate the fractional contribution of NO<sub>3</sub> to the oxidation of a dominant BVOC,  $\alpha$ -pinene (Guenther et al., 2012; J. Liebmann et al., 2018; Vermeuel et al., 2023). As detailed in Eq. (4), the overall loss rate coefficient for  $\alpha$ -pinene ( $k_{\alpha\text{-pinene}}$ ) can be calculated from the concentrations of each oxidant (OH, NO<sub>3</sub>, and O<sub>3</sub>) and the corresponding rate coefficients  $k_{x+\alpha\text{pin}}$  of  $5.3 \times 10^{-11}$ ,  $6.2 \times 10^{-12}$ , and  $9.6 \times 10^{-17}$  cm<sup>3</sup> molec.<sup>-1</sup> s<sup>-1</sup> for the reaction of OH, NO<sub>3</sub>, and O<sub>3</sub> with  $\alpha$ -pinene at 298 K, respectively (IUPAC, 2024).

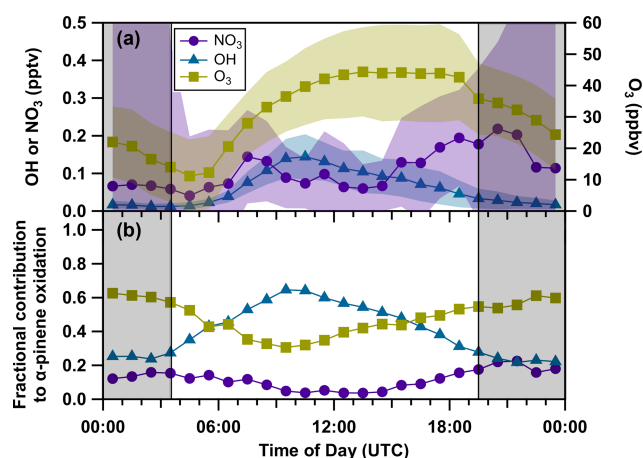

$$k_{\alpha\text{-pinene}} = k_{\text{OH}+\alpha\text{-pinene}}[\text{OH}] + k_{\text{O}_3+\alpha\text{-pinene}}[\text{O}_3] + k_{\text{NO}_3+\alpha\text{-pinene}}[\text{NO}_3]_{\text{ss}} \quad (4)$$

As measured NO<sub>3</sub> mixing ratios near ground-level were below the LOD of 2 pptv throughout the whole campaign, we derived steady-state mixing ratios, [NO<sub>3</sub>]<sub>ss</sub>, from the ratio of production ( $k_2[\text{NO}_2][\text{O}_3]$ ) and overall NO<sub>3</sub> loss rate coefficients  $k^{\text{tot}}$  (Eq. 1) (Heintz et al., 1996; Brown et al., 2003; McLaren et al., 2010; Crowley et al., 2011). Note that the OH measurements were carried out with a chemical ionization mass spectrometer (CIMS; Kukui et al., 2008; see Sect. S3) ca. 17 m apart from the MPIC container. Figure 8a depicts the campaign-averaged median mixing ratios of OH, O<sub>3</sub>, and NO<sub>3</sub> (steady state) throughout the diel cycle. Nighttime steady-state NO<sub>3</sub> mixing ratios were 0.1–0.2 pptv during late evening until midnight, decreasing to < 0.1 ppt between midnight and dawn. This is related to not only the reduced availability of O<sub>3</sub> but also the increase in  $k^{\text{VOC}}$ , both of which were usually accompanied by temperature inversions. Remarkably, daytime NO<sub>3</sub> values were similar and occasionally even higher than nighttime values, emphasizing the fact that photolysis was not the major daytime loss process for NO<sub>3</sub>. As expected, OH mixing ratios were the highest during the daytime (peak value of 0.14 pptv) but were not zero at night (0.01–0.03 pptv). Nighttime OH is formed in the oxidation of terpenes by O<sub>3</sub> and in secondary reactions of RO<sub>2</sub> and HO<sub>2</sub> (formed in the same process) with NO. Median O<sub>3</sub> mixing ratios reached ca. 44 ppbv during the day and continuously decreased to ca. 15 ppbv during the night and the early morning.

**Figure 7.** Box-and-whisker plots (full range, 25th, 50th, and 75th percentiles) of vertical profiles of (a) O<sub>3</sub>, (b) NO<sub>2</sub>, and (c) total gas-phase NO<sub>3</sub> reactivity ( $k^{\text{VOC}} + k^{\text{NO}}$ ) measured during the temperature-inverted night of 17–18 July between 20:00 and 00:00 UTC. NO<sub>3</sub> reactivities measured on top of the tower (40 m) during the nights between 18 and 23 July are also shown.

The fractional contribution of each oxidant to  $k_{\alpha\text{-pinene}}$  is presented as a median diel profile for the whole campaign in Fig. 8b. Based on the above analysis, in the summertime forested environment probed during ACROSS, NO<sub>3</sub> contributed *only* ca. 17 % to the nighttime oxidation of  $\alpha$ -pinene,

**Figure 8.** Campaign-averaged median diel profiles (1 h) of the oxidants (a)  $[\text{NO}_3]_{\text{ss}}$  (violet circles), OH (blue triangles), and  $\text{O}_3$  (dark yellow squares) and their contribution to the overall loss rate coefficient of  $\alpha$ -pinene according to Eq. (4) close to the ground (b). The nighttime period is grey-shaded. The shaded areas represent the standard deviation ( $1\sigma$ ).

a value that is exceeded by both OH (ca. 24 %) and  $\text{O}_3$  (60 %). The daytime dominance of OH and  $\text{O}_3$  (on average ca. 50 % and 41.5 %, respectively) is expected, whilst, with a contribution of 8.5 %, the diel- and campaign-averaged contribution of  $\text{NO}_3$  is still significant, which is in agreement with recent publications (Schulze et al., 2017; J. M. Liebmann et al., 2018; Mermet et al., 2021; Dewald et al., 2022) and model calculations showing that  $\text{NO}_3$  oxidizes BVOCs below the canopy level during daytime in both coniferous and deciduous forests (Forkel et al., 2006; Fuentes et al., 2007). We further note that the oxidation of BVOCs by OH,  $\text{O}_3$ , and  $\text{NO}_3$  results in greatly different products so that in terms of formation of organic nitrates,  $\text{NO}_3$ -initiated oxidation can still dominate (Liebmann et al., 2019). A detailed analysis on the role of  $\text{NO}_3$ -initiated organic nitrate formation will be presented in a future publication from the ACROSS campaign. Recall that the fractional contributions are highly dependent on the ratios between the rate coefficients of the oxidants and are thus different for other monoterpenes. As shown in the Supplement (Sect. S6), this is reflected in lower fractional contributions of  $\text{NO}_3$  to the oxidation of  $\beta$ -pinene and limonene, with values of 12.4 % and 13.5 % at night and 4.4 % and 6.2 % during the day.

Our analysis is not consistent with the generally accepted textbook paradigm that OH-initiated oxidation processes are predominant during the day and  $\text{NO}_3$ -initiated oxidation prevails at night. However, an important caveat to our analysis is the neglect of daytime transport (venting) of BVOCs out of the forest. If this proceeds at timescales that are short compared to the chemical lifetime of BVOCs, then in-canopy oxidation will be of reduced importance compared to oxidation

once BVOCs have been transported to higher levels within the boundary layer and free troposphere (Bohn, 2006).

#### 4 Conclusions and summary

During a field campaign in a peri-urban temperate (oak and pine) forest in France during a summer period in 2022, the reactivity of the  $\text{NO}_3$  radical towards VOCs was measured within the canopy (height of 5.5 m), above the canopy (height of 40 m), and on one night at several heights between 0 and 24 m.  $\text{NO}_3$  lifetimes were generally short (1–3 s), which was driven mainly by the abundance of BVOCs. Diel cycles of  $\text{NO}_3$  at 5.5 and 40 m were distinct, with the highest reactivity at 40 m occurring during the day and the highest reactivity at 5.5 m measured at nighttime. The highest nighttime reactivities were associated with high temperatures (driving the BVOC emissions) and with strong nighttime temperature inversions (preventing mixing of BVOCs and NO out of the nocturnal surface layer). At 5.5 m, BVOCs represented the dominant loss term for  $\text{NO}_3$  both during the night (70 %–80 %) and during the day ( $\sim 50$  %), which is partially a result of reduced  $\text{NO}_3$  (and  $\text{NO}_2$ ) photolysis frequencies at sub-canopy heights.  $\text{NO}_3$  reactivity decreased rapidly with height above the ground, with nocturnal lifetimes (with respect to reaction with VOCs) of  $>100$  s at 40 m and as low as 2.5 s at ground level. This gradient is driven largely by BVOC and NO emissions into a shallow, stratified near-surface layer under canopy height.

The conventional wisdom that OH is a daytime oxidant and  $\text{NO}_3$  a nighttime oxidant appears not to apply to forested regions with significant BVOC emissions where both  $\text{NO}_3$  and OH have important roles throughout the diel cycle. Hence,  $\text{NO}_3$ -initiated organic nitrate formation could become significant during the day, whereas OH-initiated nocturnal chemistry would be enhanced in such environments.

**Data availability.** All data from the ACROSS campaign including  $\text{NO}_x$  (Dewald and Crowley, 2023a, <https://doi.org/10.25326/545>; Dusanter and Jamar, 2023b, <https://across.aeris-data.fr/catalogue/?uuid=5323c4a1-ec56-4cf2-a715-fd393e6cfba6>; Xue et al., 2023, <https://doi.org/10.25326/512>),  $\text{O}_3$  (Crowley, 2023, <https://across.aeris-data.fr/catalogue/?uuid=a42b1966-a01c-4d06-9912-8922ff41f9a4>),  $\text{NO}_3$  reactivity (Dewald and Crowley, 2023b, <https://doi.org/10.25326/546>), meteorological quantities (Denjean, 2023, <https://doi.org/10.25326/437>; Dusanter and Jamar, 2023a, <https://across.aeris-data.fr/catalogue/?uuid=c9ed7224-f678-4b98-a126-11b1f3ace0f7>), peroxy radicals (Kukui, 2023b, <https://doi.org/10.25326/509>), and OH (Kukui, 2023a, <https://doi.org/10.25326/510>) can be found at <https://across.aeris-data.fr/catalogue/> (last access: 6 August 2024).

**Supplement.** The supplement related to this article is available online at: <https://doi.org/10.5194/acp-24-8983-2024-supplement>.

**Author contributions.** PD analysed the data and wrote the original draft of the manuscript and, together with JNC, revised it. CC and VM were responsible for the campaign organization with contributions from individual group leads. All authors provided measurements and commented on the paper.

**Competing interests.** At least one of the (co-)authors is a member of the editorial board of *Atmospheric Chemistry and Physics*. The peer-review process was guided by an independent editor, and the authors also have no other competing interests to declare.

**Disclaimer.** Publisher's note: Copernicus Publications remains neutral with regard to jurisdictional claims made in the text, published maps, institutional affiliations, or any other geographical representation in this paper. While Copernicus Publications makes every effort to include appropriate place names, the final responsibility lies with the authors.

**Special issue statement.** This article is part of the special issue "Atmospheric Chemistry of the Suburban Forest – multiplatform observational campaign of the chemistry and physics of mixed urban and biogenic emissions". It is not associated with a conference.

**Acknowledgements.** John N. Crowley acknowledges Chemours for the provision of an FEPD 121 sample used to coat the flow tube and the Deutsche Forschungsgemeinschaft (project MONOTONS, project no. 522970430). Simone T. Andersen thanks the Alexander von Humboldt Foundation for funding her stay at the MPIC. The ACROSS project has received funding from the French National Research Agency (ANR) under the investment programme integrated into France 2030, with reference no. ANR-17-MPGA-0002, supported by the French National program Les Enveloppes Fluides et l'Environnement (LEFE) of the Centre National de la Recherche Scientifique/Institut National des Sciences de l'Univers (CNRS/INSU). IMT Nord Europe acknowledges financial support from the CaPPA project, which is funded by the French National Research Agency (ANR) through the Programme d'Investissement d'Avenir (PIA) under contract ANR-11-LABX-0005-01, the Regional Council of Hauts-de-France, and the European Regional Development Fund (ERDF). Data from the ACROSS campaign are hosted by the French national centre for atmospheric data and services, AERIS. Alexandre Kukui acknowledges financial support from the VOLTAIRE project (ANR-10-LABX-100-01) funded by ANR through the Programme d'Investissement d'Avenir (PIA). The scientific colour map Berlin (Crameri, 2023) is used in this study to prevent visual distortion of the data and exclusion of readers with colour vision deficiencies (Crameri et al., 2020).

**Financial support.** This research has been supported by the Deutsche Forschungsgemeinschaft (grant no. 522970430), the Agence Nationale de la Recherche (grant nos. ANR-17-MPGA-0002, ANR-11-LABX-0005-01, and ANR-10-LABX-100-01), and the Alexander von Humboldt-Stiftung (postdoc fellowship).

The article processing charges for this open-access publication were covered by the Max Planck Society.

**Review statement.** This paper was edited by Eleanor Browne and reviewed by Zachary Decker and one anonymous referee.
